One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The **`ml_name`** field of the sentinel must be `NULL`.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```
typedef struct PyMemberDef {
    const char *name;
    int         type;
    int         offset;
    int         flags;
    const char *doc;
} PyMemberDef;
```

For each entry in the table, a descriptor will be constructed and

added to the type which will be able to extract a value from the instance structure. The **type** field should contain one of the type codes defined in the `structmember.h` header; the value will be used to determine how to convert Python values to and from C values. The **flags** field is used to store flags which control how the attribute can be accessed.

The following flag constants are defined in `structmember.h`; they may be combined using bitwise-OR.

Constant	Meaning
READONLY	Never writable.
PY_AUDIT_READ	Emit `object.__getattr__` audit events before reading.

Changed in version 3.10: **RESTRICTED**, **READ_RESTRICTED** and **WRITE_RESTRICTED** are deprecated. However, **READ_RESTRICTED** is an alias for **PY_AUDIT_READ**, so fields that specify either **RESTRICTED** or **READ_RESTRICTED** will also raise an audit event.

An interesting advantage of using the **tp_members** table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its **__doc__** attribute.

As with the **tp_methods** table, a sentinel entry with a **name** value of `NULL` is required.

3.3.2. Type-specific Attribute Management

For simplicity, only the char* version will be demonstrated here; the type of the name parameter is the only difference between the char* and PyObject* flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. It explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The **tp_getattr** handler is called when the object requires an

attribute look-up. It is called in the same situations where the **__getattr__()** method of a class would be called.

Here is an example:

```
static PyObject *
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    if (strcmp(name, "data") == 0)
    {
        return PyLong_FromLong(obj->data);
    }

    PyErr_Format(PyExc_AttributeError,
                 "'%.50s' object has no attribute '%.400
                 tp->tp_name, name);
    return NULL;
}
```

The **tp_setattr** handler is called when the **__setattr__()** or **__delattr__()** method of a class instance would be called. When an attribute should be deleted, the third parameter will be `NULL`. Here is an example that simply raises an exception; if this were really all you wanted, the **tp_setattr** handler should be set to `NULL`.

```
static int
newdatatype_setattr(newdatatypeobject *obj, char *name,
{
    PyErr_Format(PyExc_RuntimeError, "Read-only attribut
    return -1;
}
```

3.4. Object Comparison

```
richcmpfunc tp_richcompare;
```

The **tp_richcompare** handler is called when comparisons are needed. It is analogous to the rich comparison methods, like

__lt__(), and also called by **PyObject_RichCompare()** and **PyObject_RichCompareBool()**.

This function is called with two Python objects and the operator as arguments, where the operator is one of `Py_EQ`, `Py_NE`, `Py_LE`, `Py_GE`, `Py_LT` or `Py_GT`. It should compare the two objects with respect to the specified operator and return `Py_True` or `Py_False` if the comparison is successful, `Py_NotImplemented` to indicate that comparison is not implemented and the other object's comparison method should be tried, or `NULL` if an exception was set.

Here is a sample implementation, for a datatype that is considered equal if the size of an internal pointer is equal:

```
static PyObject *
newdatatype_richcmp(PyObject *obj1, PyObject *obj2, int
{
    PyObject *result;
    int c, size1, size2;

    /* code to make sure that both arguments are of type
       newdatatype omitted */

    size1 = obj1->obj_UnderlyingDatatypePtr->size;
    size2 = obj2->obj_UnderlyingDatatypePtr->size;

    switch (op) {
    case Py_LT: c = size1 <  size2; break;
    case Py_LE: c = size1 <= size2; break;
    case Py_EQ: c = size1 == size2; break;
    case Py_NE: c = size1 != size2; break;
    case Py_GT: c = size1 >  size2; break;
    case Py_GE: c = size1 >= size2; break;
    }
    result = c ? Py_True : Py_False;
    Py_INCREF(result);
    return result;
 }
```

3.5. Abstract Protocol Support

Python supports a variety of *abstract* 'protocols;' the specific interfaces provided to use these interfaces are documented in Abstract Objects Layer.

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-`NULL`. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```
PyNumberMethods   *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods  *tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type **`PyNumberMethods`**, **`PySequenceMethods`**, or **`PyMappingMethods`**, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the `Objects` directory of the Python source distribution.

```
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a simple example:

```
static Py_hash_t
newdatatype_hash(newdatatypeobject *obj)
{
    Py_hash_t result;
```

```
    result = obj->some_size + 32767 * obj->some_number;
    if (result == -1)
       result = -2;
    return result;
}
```

Py_hash_t is a signed integer type with a platform-varying width. Returning `-1` from **tp_hash** indicates an error, which is why you should be careful to avoid returning it when hash computation is successful, as seen above.

```
ternaryfunc tp_call;
```

This function is called when an instance of your data type is "called", for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the **tp_call** handler is invoked.

This function takes three arguments:

1. *self* is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then *self* is `obj1`.
2. *args* is a tuple containing the arguments to the call. You can use **PyArg_ParseTuple()** to extract the arguments.
3. *kwds* is a dictionary of keyword arguments that were passed. If this is non-`NULL` and you support keyword arguments, use **PyArg_ParseTupleAndKeywords()** to extract the arguments. If you do not want to support keyword arguments and this is non-`NULL`, raise a **TypeError** with a message saying that keyword arguments are not supported.

Here is a toy `tp_call` implementation:

```
static PyObject *
newdatatype_call(newdatatypeobject *self, PyObject *args
{
    PyObject *result;
    const char *arg1;
    const char *arg2;
    const char *arg3;
```

```
    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2
        return NULL;
    }
    result = PyUnicode_FromFormat(
        "Returning -- value: [%d] arg1: [%s] arg2: [%s]
        obj->obj_UnderlyingDatatypePtr->size,
        arg1, arg2, arg3);
    return result;
}

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;
```

These functions provide support for the iterator protocol. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`. **`tp_iter`** corresponds to the Python **`__iter__()`** method, while **`tp_iternext`** corresponds to the Python **`__next__()`** method.

Any iterable object must implement the **`tp_iter`** handler, which must return an iterator object. Here the same guidelines apply as for Python classes:

- For collections (such as lists and tuples) which can support multiple independent iterators, a new iterator should be created and returned by each call to **`tp_iter`**.
- Objects which can only be iterated over once (usually due to side effects of iteration, such as file objects) can implement **`tp_iter`** by returning a new reference to themselves – and should also therefore implement the **`tp_iternext`** handler.

Any iterator object should implement both **`tp_iter`** and **`tp_iternext`**. An iterator's **`tp_iter`** handler should return a new reference to the iterator. Its **`tp_iternext`** handler should return a new reference to the next object in the iteration, if there is one. If the iteration has reached the end, **`tp_iternext`** may return `NULL` without setting an exception, or it may set **`StopIteration`** *in addition* to returning `NULL`; avoiding the exception can yield

slightly better performance. If an actual error occurs, **tp_iternext** should always set an exception and return NULL.

3.6. Weak Reference Support

One of the goals of Python's weak reference implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on performance-critical objects (such as numbers).

See also

Documentation for the **weakref** module.

For an object to be weakly referencable, the extension type must do two things:

1. Include a PyObject* field in the C object structure dedicated to the weak reference mechanism. The object's constructor should leave it NULL (which is automatic when using the default **tp_alloc**).
2. Set the **tp_weaklistoffset** type member to the offset of the aforementioned field in the C object structure, so that the interpreter knows how to access and modify that field.

Concretely, here is how a trivial object structure would be augmented with the required field:

```
typedef struct {
    PyObject_HEAD
    PyObject *weakreflist;  /* List of weak references *
} TrivialObject;
```

And the corresponding member in the statically declared type object:

```
static PyTypeObject TrivialType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    /* ... other members omitted for brevity ... */
```

```
    .tp_weaklistoffset = offsetof(TrivialObject, weakref
};
```

The only further addition is that `tp_dealloc` needs to clear any weak references (by calling **`PyObject_ClearWeakRefs()`**) if the field is non-`NULL`:

```
static void
Trivial_dealloc(TrivialObject *self)
{
    /* Clear weakrefs first before calling any destructo
    if (self->weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) self);
    /* ... remainder of destruction code omitted for bre
    Py_TYPE(self)->tp_free((PyObject *) self);
}
```

3.7. More Suggestions

In order to learn how to implement any specific method for your new data type, get the CPython source code. Go to the `Objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_richcompare`). You will find examples of the function you want to implement.

When you need to verify that an object is a concrete instance of the type you are implementing, use the **`PyObject_TypeCheck()`** function. A sample of its use might be something like the following:

```
if (!PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mythi
    return NULL;
}
```

4. Building C and C++ Extensions

A C extension for CPython is a shared library (e.g. a `.so` file on Linux, `.pyd` on Windows), which exports an *initialization function*.

To be importable, the shared library must be available on **PYTHONPATH**, and must be named after the module name, with an appropriate extension. When using distutils, the correct filename is generated automatically.

The initialization function has the signature:

PyObject *PyInit_modulename(void)

It returns either a fully initialized module, or a **PyModuleDef** instance. See Initializing C modules for details.

For modules with ASCII-only names, the function must be named `PyInit_<modulename>`, with `<modulename>` replaced by the name of the module. When using Multi-phase initialization, non-ASCII module names are allowed. In this case, the initialization function name is `PyInitU_<modulename>`, with `<modulename>` encoded using Python's *punycode* encoding with hyphens replaced by underscores. In Python:

```
def initfunc_name(name):
    try:
        suffix = b'_' + name.encode('ascii')
    except UnicodeEncodeError:
        suffix = b'U_' + name.encode('punycode').replace
    return b'PyInit' + suffix
```

It is possible to export multiple modules from a single shared library by defining multiple initialization functions. However,

importing them requires using symbolic links or a custom importer, because by default only the function corresponding to the filename is found. See the *"Multiple modules in one library"* section in **PEP 489** [https://peps.python.org/pep-0489/] for details.

4.1. Building C and C++ Extensions with distutils

Extension modules can be built using distutils, which is included in Python. Since distutils also supports creation of binary packages, users don't necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, `setup.py`. This is a plain Python file, which, in the most simple case, could look like this:

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this `setup.py`, and a file `demo.c`, running

```
python setup.py build
```

will compile `demo.c`, and produce an extension module named `demo` in the `build` directory. Depending on the system, the module file will end up in a subdirectory `build/lib.system`, and may have a name like `demo.so` or `demo.pyd`.

In the `setup.py`, all execution is performed by calling the `setup` function. This takes a variable number of keyword arguments, of which the example above uses only a subset. Specifically, the

example specifies meta-information to build packages, and it specifies the contents of the package. Normally, a package will contain additional modules, like Python source modules, documentation, subpackages, etc. Please refer to the distutils documentation in Distributing Python Modules (Legacy version) to learn more about the features of distutils; this section explains building extension modules only.

It is common to pre-compute arguments to **`setup()`**, to better structure the driver script. In the example above, the `ext_modules` argument to **`setup()`** is a list of extension modules, each of which is an instance of the **`Extension`**. In the example, the instance defines an extension named `demo` which is build by compiling a single source file, `demo.c`.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    define_macros = [('MAJOR_VERSION', '
                                      ('MINOR_VERSION', '
                    include_dirs = ['/usr/local/include'
                    libraries = ['tcl83'],
                    library_dirs = ['/usr/local/lib'],
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       author = 'Martin v. Loewis',
       author_email = 'martin@v.loewis.de',
       url = 'https://docs.python.org/extending/building
       long_description = '''
This is really just a demo package.
''',
       ext_modules = [module1])
```

In this example, `setup()` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on Unix, this may result in the compilation commands

```
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC -DMA

gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/loca
```

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.

4.2. Distributing your extension modules

When an extension has been successfully built, there are three ways to use it.

End-users will typically want to install the module, they do so by running

```
python setup.py install
```

Module maintainers should produce source packages; to do so, they run

```
python setup.py sdist
```

In some cases, additional files need to be included in a source distribution; this is done through a `MANIFEST.in` file; see Specifying the files to distribute for details.

If the source distribution has been built successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

```
python setup.py bdist_rpm
python setup.py bdist_dumb
```

5. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the Unix programmer interested in producing software which can be successfully built on both Unix and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

Note

This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as `XY`; in practice, `'X'` will be the major version number and `'Y'` will be the minor version number of the Python release you're working with. For example, if you are using Python 2.2.1, `XY` will actually be `22`.

5.1. A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on Unix: use the **`distutils`** package to control the build process, or do things manually. The distutils approach works well for most extensions; documentation on using **`distutils`** to build and package extension modules is available in Distributing Python Modules (Legacy version). If you find you really

need to do things manually, it may be instructive to study the project file for the winsound [https://github.com/python/cpython/tree/3.11/PCbuild/winsound.vcxproj] standard library module.

5.2. Differences Between Unix and Windows

Unix and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In Unix, a shared object (`.so`) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (`.dll`) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory; instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In Unix, there is only one type of library file (`.a`) which contains code from several object files (`.o`). During the link step to create a shared object file (`.so`), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called `.lib`). A static library is like a Unix `.a` file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may

be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should share another block of code A. On Unix, you would *not* pass `A.a` to the linker for `B.so` and `C.so`; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building `A.dll` will also build `A.lib`. You *do* pass `A.lib` to the linker for B and C. `A.lib` does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using `import spam`; it gives you access to spam's names, but does not create a separate copy. On Unix, linking with a library is more like `from spam import *`; it does create a separate copy.

5.3. Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work. The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass `pythonXY.lib` to the linker. To build two DLLs, spam and ni (which uses C functions found in spam), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.
```

The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `Spam.dll` does not contain any Python functions (such as **`PyArg_ParseTuple()`**), but it does know how to find the Python code thanks to `pythonXY.lib`.

The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from spam, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any

other modules (including Python) to be able to see your identifiers, you have to say `_declspec(dllexport)`, as in `void _declspec(dllexport) initspam(void)` or `PyObject _declspec(dllexport) *NiGetSpamData(void)`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify *ignore default libraries*. Add the correct `msvcrtxx.lib` to the list of libraries.

1. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python — instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()`. There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to `PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

See also

Python/C API Reference Manual
The details of Python's C interface are given in this manual. A great deal of necessary information can be found here.

1.1. Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    wchar_t *program = Py_DecodeLocale(argv[0], NULL);
    if (program == NULL) {
        fprintf(stderr, "Fatal error: cannot decode argv
        exit(1);
    }
    Py_SetProgramName(program);  /* optional but recomme
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime\n"
                       "print('Today is', ctime(time()))
    if (Py_FinalizeEx() < 0) {
        exit(120);
    }
    PyMem_RawFree(program);
    return 0;
}
```

The **`Py_SetProgramName()`** function should be called before **`Py_Initialize()`** to inform the interpreter about paths to Python

run-time libraries. Next, the Python interpreter is initialized with `Py_Initialize()`, followed by the execution of a hard-coded Python script that prints the date and time. Afterwards, the `Py_FinalizeEx()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.

1.2. Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data

conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.

1.3. Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr,"Usage: call pythonfile funcname
        return 1;
    }

    Py_Initialize();
    pName = PyUnicode_DecodeFSDefault(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);
```

```
if (pModule != NULL) {
    pFunc = PyObject_GetAttrString(pModule, argv[2])
    /* pFunc is a new reference */

    if (pFunc && PyCallable_Check(pFunc)) {
        pArgs = PyTuple_New(argc - 3);
        for (i = 0; i < argc - 3; ++i) {
            pValue = PyLong_FromLong(atoi(argv[i + 3
            if (!pValue) {
                Py_DECREF(pArgs);
                Py_DECREF(pModule);
                fprintf(stderr, "Cannot convert argu
                return 1;
            }
            /* pValue reference stolen here: */
            PyTuple_SetItem(pArgs, i, pValue);
        }
        pValue = PyObject_CallObject(pFunc, pArgs);
        Py_DECREF(pArgs);
        if (pValue != NULL) {
            printf("Result of call: %ld\n", PyLong_A
            Py_DECREF(pValue);
        }
        else {
            Py_DECREF(pFunc);
            Py_DECREF(pModule);
            PyErr_Print();
            fprintf(stderr,"Call failed\n");
            return 1;
        }
    }
    else {
        if (PyErr_Occurred())
            PyErr_Print();
        fprintf(stderr, "Cannot find function \"%s\"
    }
    Py_XDECREF(pFunc);
```

```
        Py_DECREF(pModule);
    }
    else {
        PyErr_Print();
        fprintf(stderr, "Failed to load \"%s\"\n", argv[
        return 1;
    }
    if (Py_FinalizeEx() < 0) {
        return 120;
    }
    return 0;
}
```

This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you compile and link this program (let's call the finished executable **call**), and use it to execute a Python script, such as:

```
def multiply(a,b):
    print("Will compute", a, "times", b)
    c = 0
    for i in range(0, a):
        c = c + b
    return c
```

then the result should be:

```
$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6
```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```
Py_Initialize();
pName = PyUnicode_DecodeFSDefault(argv[1]);
/* Error checking of pName left out */
```

```
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using **`PyImport_Import()`**. This routine needs a Python string as its argument, which is constructed using the **`PyUnicode_FromString()`** data conversion routine.

```
pFunc = PyObject_GetAttrString(pModule, argv[2]);
/* pFunc is a new reference */

if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using **`PyObject_GetAttrString()`**. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.

1.4. Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```
static int numargs=0;

/* Return the number of arguments of the application com
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return PyLong_FromLong(numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the pro
    {NULL, NULL, 0, NULL}
};

static PyModuleDef EmbModule = {
    PyModuleDef_HEAD_INIT, "emb", NULL, -1, EmbMethods,
    NULL, NULL, NULL, NULL
};

static PyObject*
PyInit_emb(void)
{
    return PyModule_Create(&EmbModule);
}
```

Insert the above code just above the **`main()`** function. Also, insert the following two statements before the call to **`Py_Initialize()`**:

```
numargs = argc;
PyImport_AppendInittab("emb", &PyInit_emb);
```

These two lines initialize the `numargs` variable, and make the **`emb.numargs()`** function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```
import emb
print("Number of arguments", emb.numargs())
```

In a real application, the methods will expose an API of the application to Python.

1.5. Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.

1.6. Compiling and Linking under Unix-like systems

It is not necessarily trivial to find the right flags to pass to your compiler (and linker) in order to embed the Python interpreter into your application, particularly because Python needs to load library modules implemented as C dynamic extensions (`.so` files) linked against it.

To find out the required compiler and linker flags, you can execute the `python`*X*`.`*Y*`-config` script which is generated as part of the installation process (a `python3-config` script may also be available). This script has several options, of which the following will be directly useful to you:

- `pythonX.Y-config --cflags` will give you the recommended flags when compiling:

  ```
  $ /opt/bin/python3.11-config --cflags
  -I/opt/include/python3.11 -I/opt/include/python3.11
  ```

- `pythonX.Y-config --ldflags --embed` will give you the recommended flags when linking:

  ```
  $ /opt/bin/python3.11-config --ldflags --embed
  ```

```
    -L/opt/lib/python3.11/config-3.11-x86_64-linux-gnu
```

Note

To avoid confusion between several Python installations (and especially between the system Python and your own compiled Python), it is recommended that you use the absolute path to `python`*`X.Y`*`-config`, as in the above example.

If this procedure doesn't work for you (it is not guaranteed to work for all Unix-like platforms; however, we welcome bug reports) you will have to read your system's documentation about dynamic linking and/or examine Python's `Makefile` (use **`sysconfig.get_makefile_filename()`** to find its location) and compilation options. In this case, the **`sysconfig`** module is a useful tool to programmatically extract the configuration values that you will want to combine together. For example:

```
>>> import sysconfig
>>> sysconfig.get_config_var('LIBS')
'-lpthread -ldl  -lutil'
>>> sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```

Python/C API Reference Manual

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to Extending and Embedding the Python Interpreter, which describes the general principles of extension writing but does not document the API functions in detail.

Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write *extension modules* for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as *embedding* Python in an application.

Writing an extension module is a relatively well-understood process, where a "cookbook" approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

Coding standards

If you're writing C code for inclusion in CPython, you **must** follow the guidelines and standards defined in **PEP 7** [https://peps.python.org/pep-0007/]. These guidelines apply regardless of the version of Python you are contributing to. Following these conventions is not necessary for your own third party extension modules, unless you eventually expect to contribute them to Python.

Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, `<assert.h>` and `<stdlib.h>` (if available).

Note

Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

It is recommended to always define `PY_SSIZE_T_CLEAN` before including `Python.h`. See Parsing arguments and building values for a description of this macro.

All user visible names defined by Python.h (except those defined by the included standard headers) have one of the prefixes `Py` or `_Py`. Names beginning with `_Py` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

Note

User code should never define names that begin with `Py` or `_Py`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On Unix, these are located in the directories *prefix*`/include/pythonversion/` and *exec_prefix*`/include/pythonversion/`, where **prefix** and **exec_prefix** are defined

by the corresponding parameters to Python's **configure** script and *version* is `'%d.%d' % sys.version_info[:2]`. On Windows, the headers are installed in *prefix*`/include`, where **prefix** is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do *not* place the parent directories on the search path and then use `#include <pythonX.Y/Python.h>`; this will break on multi-platform builds since the platform independent headers under **prefix** include the platform specific headers from **exec_prefix**.

C++ users should note that although the API is defined entirely using C, the header files properly declare the entry points to be `extern "C"`. As a result, there is no need to do anything special to use the API from C++.

Useful macros

Several useful macros are defined in the Python header files. Many are defined closer to where they are useful (e.g. **Py_RETURN_NONE**). Others of a more general utility are defined here. This is not necessarily a complete listing.

Py_ABS(x)

Return the absolute value of `x`.

New in version 3.3.

Py_ALWAYS_INLINE

Ask the compiler to always inline a static inline function. The compiler can ignore it and decides to not inline the function.

It can be used to inline performance critical static inline functions when building Python in debug mode with function inlining disabled. For example, MSC disables function inlining when building in debug mode.

Marking blindly a static inline function with Py_ALWAYS_INLINE can result in worse performances (due to

increased code size for example). The compiler is usually smarter than the developer for the cost/benefit analysis.

If Python is built in debug mode (if the `Py_DEBUG` macro is defined), the **`Py_ALWAYS_INLINE`** macro does nothing.

It must be specified before the function return type. Usage:

```
static inline Py_ALWAYS_INLINE int random(void) { r
```

New in version 3.11.

Py_CHARMASK(c)

Argument must be a character or an integer in the range [-128, 127] or [0, 255]. This macro returns `c` cast to an `unsigned char`.

Py_DEPRECATED(version)

Use this for deprecated declarations. The macro must be placed before the symbol name.

Example:

```
Py_DEPRECATED(3.8) PyAPI_FUNC(int) Py_OldFunction(v
```

Changed in version 3.8: MSVC support was added.

Py_GETENV(s)

Like `getenv(s)`, but returns `NULL` if **`-E`** was passed on the command line (i.e. if `Py_IgnoreEnvironmentFlag` is set).

Py_MAX(x, y)

Return the maximum value between `x` and `y`.

New in version 3.3.

Py_MEMBER_SIZE(type, member)

Return the size of a structure (`type`) `member` in bytes.

New in version 3.6.

Py_MIN(x, y)

Return the minimum value between `x` and `y`.

New in version 3.3.

Py_NO_INLINE

Disable inlining on a function. For example, it reduces the C stack consumption: useful on LTO + PGO builds which heavily inline code (see bpo-33720 [https://bugs.python.org/issue?@action=redirect&bpo=33720]).

Usage:

```
Py_NO_INLINE static int random(void) { return 4; }
```

New in version 3.11.

Py_STRINGIFY(x)

Convert `x` to a C string. E.g. `Py_STRINGIFY(123)` returns `"123"`.

New in version 3.4.

Py_UNREACHABLE()

Use this when you have a code path that cannot be reached by design. For example, in the `default:` clause in a `switch` statement for which all possible values are covered in `case` statements. Use this in places where you might be tempted to put an `assert(0)` or `abort()` call.

In release mode, the macro helps the compiler to optimize the code, and avoids a warning about unreachable code. For example, the macro is implemented with `__builtin_unreachable()` on GCC in release mode.

A use for `Py_UNREACHABLE()` is following a call a function that never returns but that is not declared **`_Py_NO_RETURN`**.

If a code path is very unlikely code but can be reached under exceptional case, this macro must not be used. For example, under low memory condition or if a system call returns a value out of the expected range. In this case, it's better to report the error to the caller. If the error cannot be reported to caller, **`Py_FatalError()`** can be used.

New in version 3.7.

Py_UNUSED(arg)

Use this for unused arguments in a function definition to silence compiler warnings. Example: `int func(int a, int Py_UNUSED(b)) { return a; }`.

New in version 3.4.

PyDoc_STRVAR(name, str)

Creates a variable with name `name` that can be used in docstrings. If Python is built without docstrings, the value will be empty.

Use **`PyDoc_STRVAR`** for docstrings to support building Python without docstrings, as specified in **PEP 7** [https://peps.python.org/pep-0007/].

Example:

```
PyDoc_STRVAR(pop_doc, "Remove and return the rightm

static PyMethodDef deque_methods[] = {
    // ...
    {"pop", (PyCFunction)deque_pop, METH_NOARGS, po
    // ...
}
```

PyDoc_STR(str)

Creates a docstring for the given input string or an empty string if docstrings are disabled.

Use **PyDoc_STR** in specifying docstrings to support building Python without docstrings, as specified in **PEP 7** [https://peps.python.org/pep-0007/].

Example:

```
static PyMethodDef pysqlite_row_methods[] = {
    {"keys", (PyCFunction)pysqlite_row_keys, METH_N
        PyDoc_STR("Returns the keys of the row.")},
    {NULL, NULL}
};
```

Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type PyObject*. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type **PyObject**, only pointer variables of type PyObject* can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static **PyTypeObject** objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in The standard type hierarchy). For each of the well-known types there is a macro to check whether an object is of that type; for instance, `PyList_Check(a)` is true if (and only if) the object pointed to by *a* is a Python list.

Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a

place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object's reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other objects may be deallocated in turn, if this decrement makes their reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is "don't do that.")

Reference counts are always manipulated explicitly. The normal way is to use the macro **`Py_INCREF()`** to increment an object's reference count by one, and **`Py_DECREF()`** to decrement it by one. The **`Py_DECREF()`** macro is considerably more complex than the incref one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming `sizeof(Py_ssize_t) >= sizeof(void*)`). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possibly deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a **`Py_DECREF()`**, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with `PyObject_`, `PyNumber_`, `PySequence_` or `PyMapping_`). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call **`Py_DECREF()`** when they are done with the result; this soon becomes second nature.

Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). “Owning a reference” means being responsible for calling Py_DECREF on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref’ing it by calling **`Py_DECREF()`** or **`Py_XDECREF()`** when it’s no longer needed—or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes in a reference to an object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are

PyList_SetItem() and **PyTuple_SetItem()**, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```
PyObject *t;

t = PyTuple_New(3);
PyTuple_SetItem(t, 0, PyLong_FromLong(1L));
PyTuple_SetItem(t, 1, PyLong_FromLong(2L));
PyTuple_SetItem(t, 2, PyUnicode_FromString("three"));
```

Here, **PyLong_FromLong()** returns a new reference which is immediately stolen by **PyTuple_SetItem()**. When you want to keep using an object although the reference to it will be stolen, use **Py_INCREF()** to grab another reference before calling the reference-stealing function.

Incidentally, **PyTuple_SetItem()** is the *only* way to set tuple items; **PySequence_SetItem()** and **PyObject_SetItem()** refuse to do this since tuples are an immutable data type. You should only use **PyTuple_SetItem()** for tuples that you are creating yourself.

Equivalent code for populating a list can be written using **PyList_New()** and **PyList_SetItem()**.

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There's a generic function, **Py_BuildValue()**, that can create most common objects from C values, directed by a *format string*. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
```

```
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use **PyObject_SetItem()** and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don't have to increment a reference count so you can give a reference away ("have it be stolen"). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```
int
set_all(PyObject *target, PyObject *item)
{
    Py_ssize_t i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyLong_FromSsize_t(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0) {
            Py_DECREF(index);
            return -1;
        }
        Py_DECREF(index);
    }
    return 0;
}
```

The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like **PyObject_GetItem()** and

PySequence_GetItem(), always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only — *the plumage* (the type of the object passed as an argument to the function) *doesn't enter into it!* Thus, if you extract an item from a list using **PyList_GetItem()**, you don't own the reference — but if you obtain the same item from the same list using **PySequence_GetItem()** (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using **PyList_GetItem()**, and once using **PySequence_GetItem()**.

```
long
sum_list(PyObject *list)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyLong_Check(item)) continue; /* Skip non-i
        value = PyLong_AsLong(item);
        if (value == -1 && PyErr_Occurred())
            /* Integer too big to fit in a C long, bail
            return -1;
        total += value;
    }
    return total;
}

long
sum_sequence(PyObject *sequence)
```

```
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)
            return -1; /* Not a sequence, or other failu
        if (PyLong_Check(item)) {
            value = PyLong_AsLong(item);
            Py_DECREF(item);
            if (value == -1 && PyErr_Occurred())
                /* Integer too big to fit in a C long, b
                return -1;
            total += value;
        }
        else {
            Py_DECREF(item); /* Discard reference owners
        }
    }
    return total;
}
```

Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as int, long, double and char*. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.

type Py_ssize_t

Part of the Stable ABI.
A signed integral type such that `sizeof(Py_ssize_t) ==`

`sizeof(size_t)`. C99 doesn't define such a thing directly (size_t is an unsigned integral type). See **PEP 353** [https://peps.python.org/pep-0353/] for details. `PY_SSIZE_T_MAX` is the largest positive value of type **`Py_ssize_t`**.

Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator. If not documented otherwise, this indicator is either `NULL` or `-1`, depending on the function's return type. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with **`PyErr_Occurred()`**. These exceptions are always explicitly documented.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function **`PyErr_Occurred()`** can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and `NULL` otherwise. There are a number of functions to set the exception state: **`PyErr_SetString()`** is the most common (though not the most general) function to set the exception state, and **`PyErr_Clear()`** clears the exception state.

The full exception state consists of three objects (all of which can be `NULL`): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python result

of `sys.exc_info()`; however, they are not the same: the Python objects represent the last exception being handled by a Python **`try`** … **`except`** statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to `sys.exc_info()` and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the exception state from Python code is to call the function **`sys.exc_info()`**, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should *not* set another exception — that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the **`sum_sequence()`** example above. It so happens that this example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```
int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *increment
    int rv = -1; /* Return value initialized to -1 (fail

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyLong_FromLong(0L);
        if (item == NULL)
            goto error;
    }
    const_one = PyLong_FromLong(1L);
    if (const_one == NULL)
        goto error;

    incremented_item = PyNumber_Add(item, const_one);
    if (incremented_item == NULL)
        goto error;

    if (PyObject_SetItem(dict, key, incremented_item) <
        goto error;
    rv = 0; /* Success */
    /* Continue with cleanup code */

 error:
    /* Cleanup code, shared by success and failure path

    /* Use Py_XDECREF() to ignore NULL references */
    Py_XDECREF(item);
```

```
    Py_XDECREF(const_one);
    Py_XDECREF(incremented_item);

    return rv; /* -1 for error, 0 for success */
}
```

This example represents an endorsed use of the `goto` statement in C! It illustrates the use of **`PyErr_ExceptionMatches()`** and **`PyErr_Clear()`** to handle specific exceptions, and the use of **`Py_XDECREF()`** to dispose of owned references that may be `NULL` (note the `'X'` in the name; **`Py_DECREF()`** would crash when confronted with a `NULL` reference). It is important that the variables used to hold owned references are initialized to `NULL` for this to work; likewise, the proposed return value is initialized to `-1` (failure) and only set to success after the final call made is successful.

Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is **`Py_Initialize()`**. This initializes the table of loaded modules, and creates the fundamental modules **`builtins`**, **`__main__`**, and **`sys`**. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, setting **`PyConfig.argv`** and **`PyConfig.parse_argv`** must be set: see Python Initialization Configuration.

On most systems (in particular, on Unix and Windows, although the details are slightly different), **`Py_Initialize()`** calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python

library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/pythonX.Y` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable **`PATH`**).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/pythonX.Y`. (In fact, this particular path is also the "fallback" location, used when no executable file named `python` is found along **`PATH`**.) The user can override this behavior by setting the environment variable **`PYTHONHOME`**, or insert additional directories in front of the standard path by setting **`PYTHONPATH`**.

The embedding application can steer the search by calling `Py_SetProgramName(file)` *before* calling **`Py_Initialize()`**. Note that **`PYTHONHOME`** still overrides this and **`PYTHONPATH`** is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of **`Py_GetPath()`**, **`Py_GetPrefix()`**, **`Py_GetExecPrefix()`**, and **`Py_GetProgramFullPath()`** (all defined in `Modules/getpath.c`).

Sometimes, it is desirable to "uninitialize" Python. For instance, the application may want to start over (make another call to **`Py_Initialize()`**) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling **`Py_FinalizeEx()`**. The function **`Py_IsInitialized()`** returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that **`Py_FinalizeEx()`** does *not* free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.

Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file `Misc/SpecialBuilds.txt` in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently used builds will be described in the remainder of this section.

Compiling the interpreter with the **`Py_DEBUG`** macro defined produces what is generally meant by a debug build of Python. **`Py_DEBUG`** is enabled in the Unix build by adding **`--with-pydebug`** to the `./configure` command. It is also implied by the presence of the not-Python-specific **`_DEBUG`** macro. When **`Py_DEBUG`** is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, extra checks are performed, see Python Debug Build.

Defining **`Py_TRACE_REFS`** enables reference tracing (see the **`configure --with-trace-refs option`**). When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every **`PyObject`**. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.)

Please refer to `Misc/SpecialBuilds.txt` in the Python source distribution for more detailed information.

C API Stability

Python's C API is covered by the Backwards Compatibility Policy, **PEP 387** [https://peps.python.org/pep-0387/]. While the C API will change with every minor release (e.g. from 3.9 to 3.10), most changes will be source-compatible, typically by only adding new API. Changing existing API or removing API is only done after a deprecation period or to fix serious issues.

CPython's Application Binary Interface (ABI) is forward- and backwards-compatible across a minor release (if these are compiled the same way; see Platform Considerations below). So, code compiled for Python 3.10.0 will work on 3.10.8 and vice versa, but will need to be compiled separately for 3.9.x and 3.10.x.

Names prefixed by an underscore, such as `_Py_InternalState`, are private API that can change without notice even in patch releases.

Stable Application Binary Interface

Python 3.2 introduced the *Limited API*, a subset of Python's C API. Extensions that only use the Limited API can be compiled once and work with multiple versions of Python. Contents of the Limited API are listed below.

To enable this, Python provides a *Stable ABI*: a set of symbols that will remain compatible across Python 3.x versions. The Stable ABI contains symbols exposed in the Limited API, but also other ones – for example, functions necessary to support older versions of the Limited API.

(For simplicity, this document talks about *extensions*, but the Limited API and Stable ABI work the same way for all uses of the API – for example, embedding Python.)

Py_LIMITED_API

> Define this macro before including `Python.h` to opt in to only use the Limited API, and to select the Limited API version.
>
> Define `Py_LIMITED_API` to the value of **`PY_VERSION_HEX`** corresponding to the lowest Python version your extension supports. The extension will work without recompilation with all Python 3 releases from the specified one onward, and can use Limited API introduced up to that version.
>
> Rather than using the `PY_VERSION_HEX` macro directly, hardcode a minimum minor version (e.g. `0x030A0000` for Python 3.10) for stability when compiling with future Python versions.
>
> You can also define `Py_LIMITED_API` to `3`. This works the same as `0x03020000` (Python 3.2, the version that introduced Limited API).

On Windows, extensions that use the Stable ABI should be linked against `python3.dll` rather than a version-specific library such as `python39.dll`.

On some platforms, Python will look for and load shared library files named with the `abi3` tag (e.g. `mymodule.abi3.so`). It does not check if such extensions conform to a Stable ABI. The user (or their packaging tools) need to ensure that, for example, extensions built with the 3.10+ Limited API are not installed for lower versions of Python.

All functions in the Stable ABI are present as functions in Python's shared library, not solely as macros. This makes them usable from languages that don't use the C preprocessor.

Limited API Scope and Performance

The goal for the Limited API is to allow everything that is possible with the full C API, but possibly with a performance penalty.

For example, while **`PyList_GetItem()`** is available, its "unsafe" macro variant **`PyList_GET_ITEM()`** is not. The macro can be faster because it can rely on version-specific implementation details of the list object.

Without `Py_LIMITED_API` defined, some C API functions are inlined or replaced by macros. Defining `Py_LIMITED_API` disables this inlining, allowing stability as Python's data structures are improved, but possibly reducing performance.

By leaving out the `Py_LIMITED_API` definition, it is possible to compile a Limited API extension with a version-specific ABI. This can improve performance for that Python version, but will limit compatibility. Compiling with `Py_LIMITED_API` will then yield an extension that can be distributed where a version-specific one is not available – for example, for prereleases of an upcoming Python version.

Limited API Caveats

Note that compiling with `Py_LIMITED_API` is *not* a complete guarantee that code conforms to the Limited API or the Stable ABI. `Py_LIMITED_API` only covers definitions, but an API also includes other issues, such as expected semantics.

One issue that `Py_LIMITED_API` does not guard against is calling a function with arguments that are invalid in a lower Python version. For example, consider a function that starts accepting `NULL` for an argument. In Python 3.9, `NULL` now selects a default behavior, but in Python 3.8, the argument will be used directly, causing a `NULL` dereference and crash. A similar argument works for fields of structs.

Another issue is that some struct fields are currently not hidden when `Py_LIMITED_API` is defined, even though they're part of the Limited API.

For these reasons, we recommend testing an extension with *all* minor Python versions it supports, and preferably to build with the *lowest* such version.

We also recommend reviewing documentation of all used API to check if it is explicitly part of the Limited API. Even with `Py_LIMITED_API` defined, a few private declarations are exposed for technical reasons (or even unintentionally, as bugs).

Also note that the Limited API is not necessarily stable: compiling with `Py_LIMITED_API` with Python 3.8 means that the extension will run with Python 3.12, but it will not necessarily *compile* with Python 3.12. In particular, parts of the Limited API may be deprecated and removed, provided that the Stable ABI stays stable.

Platform Considerations

ABI stability depends not only on Python, but also on the compiler used, lower-level libraries and compiler options. For the purposes of the Stable ABI, these details define a “platform”. They usually depend on the OS type and processor architecture

It is the responsibility of each particular distributor of Python to ensure that all Python versions on a particular platform are built in a way that does not break the Stable ABI. This is the case with Windows and macOS releases from `python.org` and many third-party distributors.

Contents of Limited API

Currently, the Limited API includes the following items:

- **PyAIter_Check()**
- **PyArg_Parse()**
- **PyArg_ParseTuple()**
- **PyArg_ParseTupleAndKeywords()**
- **PyArg_UnpackTuple()**
- **PyArg_VaParse()**
- **PyArg_VaParseTupleAndKeywords()**
- **PyArg_ValidateKeywordArguments()**
- **PyBaseObject_Type**
- **PyBool_FromLong()**

- PyBool_Type
- PyBuffer_FillContiguousStrides()
- PyBuffer_FillInfo()
- PyBuffer_FromContiguous()
- PyBuffer_GetPointer()
- PyBuffer_IsContiguous()
- PyBuffer_Release()
- PyBuffer_SizeFromFormat()
- PyBuffer_ToContiguous()
- PyByteArrayIter_Type
- PyByteArray_AsString()
- PyByteArray_Concat()
- PyByteArray_FromObject()
- PyByteArray_FromStringAndSize()
- PyByteArray_Resize()
- PyByteArray_Size()
- PyByteArray_Type
- PyBytesIter_Type
- PyBytes_AsString()
- PyBytes_AsStringAndSize()
- PyBytes_Concat()
- PyBytes_ConcatAndDel()
- PyBytes_DecodeEscape()
- PyBytes_FromFormat()
- PyBytes_FromFormatV()
- PyBytes_FromObject()
- PyBytes_FromString()
- PyBytes_FromStringAndSize()
- PyBytes_Repr()
- PyBytes_Size()
- PyBytes_Type
- PyCFunction
- PyCFunctionWithKeywords
- PyCFunction_Call()
- PyCFunction_GetFlags()
- PyCFunction_GetFunction()

The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are **`Py_eval_input`**, **`Py_file_input`**, and **`Py_single_input`**. These are described following the functions which accept them as parameters.

Note also that several of these functions take FILE* parameters. One particular issue which needs to be handled carefully is that the FILE structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that FILE* parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

int Py_Main(int argc, wchar_t **argv)

Part of the Stable ABI.
The main program for the standard interpreter. This is made available for programs which embed Python. The *argc* and *argv* parameters should be prepared exactly as those which are passed to a C program's **`main()`** function (converted to wchar_t according to the user's locale). It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be `0` if the interpreter exits normally (i.e., without an exception), `1` if the interpreter exits due to an exception, or `2` if the parameter list does not represent a valid Python command line.

Note that if an otherwise unhandled **`SystemExit`** is raised, this function will not return `1`, but exit the process, as long

as `Py_InspectFlag` is not set.

int Py_BytesMain(int argc, char **argv)

Part of the Stable ABI since version 3.8.
Similar to **`Py_Main()`** but *argv* is an array of bytes strings.

New in version 3.8.

int PyRun_AnyFile(FILE *fp, const char *filename)

This is a simplified interface to **`PyRun_AnyFileExFlags()`** below, leaving *closeit* set to `0` and *flags* set to `NULL`.

int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

This is a simplified interface to **`PyRun_AnyFileExFlags()`** below, leaving the *closeit* argument set to `0`.

int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)

This is a simplified interface to **`PyRun_AnyFileExFlags()`** below, leaving the *flags* argument set to `NULL`.

int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

If *fp* refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of **`PyRun_InteractiveLoop()`**, otherwise return the result of **`PyRun_SimpleFile()`**. *filename* is decoded from the filesystem encoding (**`sys.getfilesystemencoding()`**). If *filename* is `NULL`, this function uses `"???"` as the filename. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

int PyRun_SimpleString(const char *command)

This is a simplified interface to **`PyRun_SimpleStringFlags()`** below, leaving the

PyCompilerFlags* argument set to `NULL`.

int PyRun_SimpleStringFlags(const char *command, PyCompilerFlags *flags)

Executes the Python source code from *command* in the **__main__** module according to the *flags* argument. If **__main__** does not already exist, it is created. Returns `0` on success or `-1` if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of *flags*, see below.

Note that if an otherwise unhandled **SystemExit** is raised, this function will not return `-1`, but exit the process, as long as `Py_InspectFlag` is not set.

int PyRun_SimpleFile(FILE *fp, const char *filename)

This is a simplified interface to **PyRun_SimpleFileExFlags()** below, leaving *closeit* set to `0` and *flags* set to `NULL`.

int PyRun_SimpleFileEx(FILE *fp, const char *filename, int closeit)

This is a simplified interface to **PyRun_SimpleFileExFlags()** below, leaving *flags* set to `NULL`.

int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

Similar to **PyRun_SimpleStringFlags()**, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from filesystem encoding and error handler. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

Note

On Windows, *fp* should be opened as binary mode (e.g. `fopen(filename, "rb")`). Otherwise, Python may not

handle script file with LF line ending correctly.

int PyRun_InteractiveOne(FILE *fp, const char *filename)

This is a simplified interface to **`PyRun_InteractiveOneFlags()`** below, leaving *flags* set to `NULL`.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute a single statement from a file associated with an interactive device according to the *flags* argument. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the filesystem encoding and error handler.

Returns `0` when the input was executed successfully, `-1` if there was an exception, or an error code from the `errcode.h` include file distributed as part of Python if there was a parse error. (Note that `errcode.h` is not included by `Python.h`, so must be included specifically if needed.)

int PyRun_InteractiveLoop(FILE *fp, const char *filename)

This is a simplified interface to **`PyRun_InteractiveLoopFlags()`** below, leaving *flags* set to `NULL`.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the filesystem encoding and error handler. Returns `0` at EOF or a negative number upon failure.

int (*PyOS_InputHook)(void)

Part of the Stable ABI.

Can be set to point to a function with the prototype `int func(void)`. The function will be called when Python's interpreter prompt is about to become idle and wait for user input from the terminal. The return value is ignored. Overriding this hook can be used to integrate the interpreter's prompt with other event loops, as done in the `Modules/_tkinter.c` in the Python source code.

char *(*PyOS_ReadlineFunctionPointer)(FILE*, FILE*, const char*)

Can be set to point to a function with the prototype `char *func(FILE *stdin, FILE *stdout, char *prompt)`, overriding the default function used to read a single line of input at the interpreter's prompt. The function is expected to output the string *prompt* if it's not `NULL`, and then read a line of input from the provided standard input file, returning the resulting string. For example, The **`readline`** module sets this hook to provide line-editing and tab-completion features.

The result must be a string allocated by **`PyMem_RawMalloc()`** or **`PyMem_RawRealloc()`**, or `NULL` if an error occurred.

Changed in version 3.4: The result must be allocated by **`PyMem_RawMalloc()`** or **`PyMem_RawRealloc()`**, instead of being allocated by **`PyMem_Malloc()`** or **`PyMem_Realloc()`**.

PyObject *PyRun_String(const char *str, int start, PyObject *globals, PyObject *locals)

Return value: New reference.
This is a simplified interface to **`PyRun_StringFlags()`** below, leaving *flags* set to `NULL`.

PyObject *PyRun_StringFlags(const char *str, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

Return value: New reference.
Execute Python source code from *str* in the context specified

by the objects *globals* and *locals* with the compiler flags specified by *flags*. *globals* must be a dictionary; *locals* can be any object that implements the mapping protocol. The parameter *start* specifies the start token that should be used to parse the source code.

Returns the result of executing the code as a Python object, or `NULL` if an exception was raised.

PyObject *PyRun_File(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *closeit* set to `0` and *flags* set to `NULL`.

PyObject *PyRun_FileEx(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *flags* set to `NULL`.

PyObject *PyRun_FileFlags(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *closeit* set to `0`.

PyObject *PyRun_FileExFlags(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit, PyCompilerFlags *flags)

Return value: New reference.
Similar to **`PyRun_StringFlags()`**, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the filesystem encoding and error handler. If *closeit* is true, the file is closed before **`PyRun_FileExFlags()`** returns.

PyObject *Py_CompileString(const char *str, const char *filename, int start)

Return value: New reference. Part of the Stable ABI.
This is a simplified interface to **`Py_CompileStringFlags()`** below, leaving *flags* set to `NULL`.

PyObject *Py_CompileStringFlags(const char *str, const char *filename, int start, PyCompilerFlags *flags)

Return value: New reference.
This is a simplified interface to **`Py_CompileStringExFlags()`** below, with *optimize* set to `-1`.

PyObject *Py_CompileStringObject(const char *str, PyObject *filename, int start, PyCompilerFlags *flags, int optimize)

Return value: New reference.
Parse and compile the Python source code in *str*, returning the resulting code object. The start token is given by *start*; this can be used to constrain the code which can be compiled and should be **`Py_eval_input`**, **`Py_file_input`**, or **`Py_single_input`**. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or **`SyntaxError`** exception messages. This returns `NULL` if the code cannot be parsed or compiled.

The integer *optimize* specifies the optimization level of the compiler; a value of `-1` selects the optimization level of the interpreter as given by **`-O`** options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

New in version 3.4.

PyObject *Py_CompileStringExFlags(const char *str, const char *filename, int start, PyCompilerFlags *flags, int optimize)

Return value: New reference.

Like **`Py_CompileStringObject()`**, but *filename* is a byte string decoded from the filesystem encoding and error handler.

New in version 3.2.

PyObject *PyEval_EvalCode(PyObject *co, PyObject *globals, PyObject *locals)

Return value: New reference. Part of the Stable ABI.
This is a simplified interface to **`PyEval_EvalCodeEx()`**, with just the code object, and global and local variables. The other arguments are set to `NULL`.

PyObject *PyEval_EvalCodeEx(PyObject *co, PyObject *globals, PyObject *locals, PyObject *const *args, int argcount, PyObject *const *kws, int kwcount, PyObject *const *defs, int defcount, PyObject *kwdefs, PyObject *closure)

Return value: New reference. Part of the Stable ABI.
Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of a dictionary of global variables, a mapping object of local variables, arrays of arguments, keywords and defaults, a dictionary of default values for keyword-only arguments and a closure tuple of cells.

PyObject *PyEval_EvalFrame(PyFrameObject *f)

Return value: New reference. Part of the Stable ABI.
Evaluate an execution frame. This is a simplified interface to **`PyEval_EvalFrameEx()`**, for backward compatibility.

PyObject *PyEval_EvalFrameEx(PyFrameObject *f, int throwflag)

Return value: New reference. Part of the Stable ABI.
This is the main, unvarnished function of Python interpretation. The code object associated with the execution frame *f* is executed, interpreting bytecode and executing calls as needed. The additional *throwflag* parameter can mostly be ignored - if true, then it causes an exception to immediately

be thrown; this is used for the **throw()** methods of generator objects.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

int PyEval_MergeCompilerFlags(PyCompilerFlags *cf)

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

int Py_eval_input

The start symbol from the Python grammar for isolated expressions; for use with **Py_CompileString()**.

int Py_file_input

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with **Py_CompileString()**. This is the symbol to use when compiling arbitrarily long Python source code.

int Py_single_input

The start symbol from the Python grammar for a single statement; for use with **Py_CompileString()**. This is the symbol used for the interactive interpreter loop.

struct PyCompilerFlags

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify *flags*.

Whenever `PyCompilerFlags *flags` is `NULL`, **cf_flags** is treated as equal to `0`, and any modification due to `from __future__ import` is discarded.

int cf_flags

Compiler flags.

int cf_feature_version

cf_feature_version is the minor Python version. It should be initialized to `PY_MINOR_VERSION`.

The field is ignored by default, it is used if and only if `PyCF_ONLY_AST` flag is set in *cf_flags*.

Changed in version 3.8: Added *cf_feature_version* field.

int CO_FUTURE_DIVISION

This bit can be set in *flags* to cause division operator `/` to be interpreted as "true division" according to **PEP 238** [https://peps.python.org/pep-0238/].

Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void Py_INCREF(PyObject *o)

Increment the reference count for object *o*.

This function is usually used to convert a borrowed reference to a strong reference in-place. The **Py_NewRef()** function can be used to create a new strong reference.

The object must not be NULL; if you aren't sure that it isn't NULL, use **Py_XINCREF()**.

void Py_XINCREF(PyObject *o)

Increment the reference count for object *o*. The object may be NULL, in which case the macro has no effect.

See also **Py_XNewRef()**.

PyObject *Py_NewRef(PyObject *o)

Part of the Stable ABI since version 3.10.
Create a new strong reference to an object: increment the reference count of the object *o* and return the object *o*.

When the strong reference is no longer needed, **Py_DECREF()** should be called on it to decrement the object reference count.

The object *o* must not be NULL; use **Py_XNewRef()** if *o* can be NULL.

For example:

```
Py_INCREF(obj);
```

```
self->attr = obj;
```

can be written as:

```
self->attr = Py_NewRef(obj);
```

See also **Py_INCREF()**.

New in version 3.10.

PyObject *Py_XNewRef(PyObject *o)

Part of the Stable ABI since version 3.10.
Similar to **Py_NewRef()**, but the object *o* can be NULL.

If the object *o* is `NULL`, the function just returns `NULL`.

New in version 3.10.

void Py_DECREF(PyObject *o)

Decrement the reference count for object *o*.

If the reference count reaches zero, the object's type's deallocation function (which must not be `NULL`) is invoked.

This function is usually used to delete a strong reference before exiting its scope.

The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use **Py_XDECREF()**.

Warning

The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a **__del__()** method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before **Py_DECREF()** is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable,

update the list data structure, and then call **Py_DECREF()** for the temporary variable.

void Py_XDECREF(PyObject *o)

Decrement the reference count for object *o*. The object may be NULL, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, and the same warning applies.

void Py_CLEAR(PyObject *o)

Decrement the reference count for object *o*. The object may be NULL, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, except that the argument is also set to NULL. The warning for **Py_DECREF()** does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to NULL before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the reference count of an object that might be traversed during garbage collection.

void Py_IncRef(PyObject *o)

Part of the Stable ABI.
Increment the reference count for object *o*. A function version of **Py_XINCREF()**. It can be used for runtime dynamic embedding of Python.

void Py_DecRef(PyObject *o)

Part of the Stable ABI.
Decrement the reference count for object *o*. A function version of **Py_XDECREF()**. It can be used for runtime dynamic embedding of Python.

The following functions or macros are only for use within the

interpreter core: **`_Py_Dealloc()`**, **`_Py_ForgetReference()`**, **`_Py_NewReference()`**, as well as the global variable **`_Py_RefTotal`**.

Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the POSIX **`errno`** variable: there is a global indicator (per thread) of the last error that occurred. Most C API functions don't clear this on success, but will set it to indicate the cause of the error on failure. Most C API functions also return an error indicator, usually `NULL` if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*` functions return `1` for success and `0` for failure).

Concretely, the error indicator consists of three object pointers: the exception's type, the exception's value, and the traceback object. Any of those pointers can be `NULL` if non-set (although some combinations are forbidden, for example you can't have a non-`NULL` traceback if the exception type is `NULL`).

When a function must fail because some function it called failed, it generally doesn't set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should *not* continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

Note

The error indicator is **not** the result of `sys.exc_info()`. The former corresponds to an exception that is not yet caught (and is therefore still propagating), while the latter returns an exception after it is caught (and has therefore stopped propagating).

Printing and clearing

void PyErr_Clear()

Part of the Stable ABI.
Clear the error indicator. If the error indicator is not set, there is no effect.

void PyErr_PrintEx(int set_sys_last_vars)

Part of the Stable ABI.
Print a standard traceback to `sys.stderr` and clear the error indicator. **Unless** the error is a `SystemExit`, in that case no traceback is printed and the Python process will exit with the error code specified by the `SystemExit` instance.

Call this function **only** when the error indicator is set. Otherwise it will cause a fatal error!

If *set_sys_last_vars* is nonzero, the variables **`sys.last_type`**, **`sys.last_value`** and **`sys.last_traceback`** will be set to the type, value and traceback of the printed exception, respectively.

void PyErr_Print()

Part of the Stable ABI.
Alias for `PyErr_PrintEx(1)`.

void PyErr_WriteUnraisable(PyObject *obj)

Part of the Stable ABI.
Call **`sys.unraisablehook()`** using the current exception and *obj* argument.

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an **`__del__()`** method.

The function is called with a single argument *obj* that

identifies the context in which the unraisable exception occurred. If possible, the repr of *obj* will be printed in the warning message.

An exception must be set when calling this function.

Raising exceptions

These functions help you set the current thread's error indicator. For convenience, some of these functions will always return a `NULL` pointer for use in a `return` statement.

void PyErr_SetString(PyObject *type, const char *message)

Part of the Stable ABI.
This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. **`PyExc_RuntimeError`**. You need not increment its reference count. The second argument is an error message; it is decoded from `'utf-8'`.

void PyErr_SetObject(PyObject *type, PyObject *value)

Part of the Stable ABI.
This function is similar to **`PyErr_SetString()`** but lets you specify an arbitrary Python object for the "value" of the exception.

PyObject *PyErr_Format(PyObject *exception, const char *format, ...)

Return value: Always NULL. Part of the Stable ABI.
This function sets the error indicator and returns `NULL`. *exception* should be a Python exception class. The *format* and subsequent parameters help format the error message; they have the same meaning and values as in **`PyUnicode_FromFormat()`**. *format* is an ASCII-encoded string.

PyObject *PyErr_FormatV(PyObject *exception, const char *format,

va_list vargs)

Return value: Always NULL. Part of the Stable ABI since version 3.5.
Same as **PyErr_Format()**, but taking a **va_list** argument rather than a variable number of arguments.

New in version 3.5.

void PyErr_SetNone(PyObject *type)

Part of the Stable ABI.
This is a shorthand for `PyErr_SetObject(type, Py_None)`.

int PyErr_BadArgument()

Part of the Stable ABI.
This is a shorthand for `PyErr_SetString(PyExc_TypeError, message)`, where *message* indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

PyObject *PyErr_NoMemory()

Return value: Always NULL. Part of the Stable ABI.
This is a shorthand for `PyErr_SetNone(PyExc_MemoryError)`; it returns `NULL` so an object allocation function can write `return PyErr_NoMemory();` when it runs out of memory.

PyObject *PyErr_SetFromErrno(PyObject *type)

Return value: Always NULL. Part of the Stable ABI.
This is a convenience function to raise an exception when a C library function has returned an error and set the C variable **errno**. It constructs a tuple object whose first item is the integer **errno** value and whose second item is the corresponding error message (gotten from **strerror()**), and then calls `PyErr_SetObject(type, object)`. On Unix, when the **errno** value is **EINTR**, indicating an interrupted system call, this calls **PyErr_CheckSignals()**,

and if that set the error indicator, leaves it set to that. The function always returns `NULL`, so a wrapper function around a system call can write `return PyErr_SetFromErrno(type);` when the system call returns an error.

PyObject *PyErr_SetFromErrnoWithFilenameObject(PyObject *type, PyObject *filenameObject)

Return value: Always NULL. Part of the Stable ABI.
Similar to **`PyErr_SetFromErrno()`**, with the additional behavior that if *filenameObject* is not `NULL`, it is passed to the constructor of *type* as a third parameter. In the case of **`OSError`** exception, this is used to define the **`filename`** attribute of the exception instance.

PyObject *PyErr_SetFromErrnoWithFilenameObjects(PyObject *type, PyObject *filenameObject, PyObject *filenameObject2)

Return value: Always NULL. Part of the Stable ABI since version 3.7.
Similar to **`PyErr_SetFromErrnoWithFilenameObject()`**, but takes a second filename object, for raising errors when a function that takes two filenames fails.

New in version 3.4.

PyObject *PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)

Return value: Always NULL. Part of the Stable ABI.
Similar to **`PyErr_SetFromErrnoWithFilenameObject()`**, but the filename is given as a C string. *filename* is decoded from the filesystem encoding and error handler.

PyObject *PyErr_SetFromWindowsErr(int ierr)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.

This is a convenience function to raise **WindowsError**. If called with *ierr* of `0`, the error code returned by a call to **GetLastError()** is used instead. It calls the Win32 function **FormatMessage()** to retrieve the Windows description of error code given by *ierr* or **GetLastError()**, then it constructs a tuple object whose first item is the *ierr* value and whose second item is the corresponding error message (gotten from **FormatMessage()**), and then calls `PyErr_SetObject(PyExc_WindowsError, object)`. This function always returns `NULL`.

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErr(PyObject *type, int ierr)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **PyErr_SetFromWindowsErr()**, with an additional parameter specifying the exception type to be raised.

Availability: Windows.

PyObject *PyErr_SetFromWindowsErrWithFilename(int ierr, const char *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **PyErr_SetFromWindowsErrWithFilenameObject()**, but the filename is given as a C string. *filename* is decoded from the filesystem encoding (**os.fsdecode()**).

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErrWithFilenameObject(PyObject *type, int ierr, PyObject *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.

Similar to **PyErr_SetFromWindowsErrWithFilenameObject()**, with an additional parameter specifying the exception type to be raised.

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErrWithFilenameObjects(PyObject *type, int ierr, PyObject *filename, PyObject *filename2)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **PyErr_SetExcFromWindowsErrWithFilenameObject()**, but accepts a second filename object.

Availability: Windows.

New in version 3.4.

PyObject *PyErr_SetExcFromWindowsErrWithFilename(PyObject *type, int ierr, const char *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **PyErr_SetFromWindowsErrWithFilename()**, with an additional parameter specifying the exception type to be raised.

Availability: Windows.

PyObject *PyErr_SetImportError(PyObject *msg, PyObject *name, PyObject *path)

Return value: Always NULL. Part of the Stable ABI since version 3.7.
This is a convenience function to raise **ImportError**. *msg* will be set as the exception's message string. *name* and *path*, both of which can be `NULL`, will be set as the **ImportError**'s respective `name` and `path` attributes.

New in version 3.3.

PyObject *PyErr_SetImportErrorSubclass(PyObject *exception, PyObject *msg, PyObject *name, PyObject *path)

Return value: Always NULL. Part of the Stable ABI since version 3.6.
Much like **PyErr_SetImportError()** but this function allows for specifying a subclass of **ImportError** to raise.

New in version 3.6.

void PyErr_SyntaxLocationObject(PyObject *filename, int lineno, int col_offset)

Set file, line, and offset information for the current exception. If the current exception is not a **SyntaxError**, then it sets additional attributes, which make the exception printing subsystem think the exception is a **SyntaxError**.

New in version 3.4.

void PyErr_SyntaxLocationEx(const char *filename, int lineno, int col_offset)

Part of the Stable ABI since version 3.7.
Like **PyErr_SyntaxLocationObject()**, but *filename* is a byte string decoded from the filesystem encoding and error handler.

New in version 3.2.

void PyErr_SyntaxLocation(const char *filename, int lineno)

Part of the Stable ABI.
Like **PyErr_SyntaxLocationEx()**, but the *col_offset* parameter is omitted.

void PyErr_BadInternalCall()

Part of the Stable ABI.
This is a shorthand for

`PyErr_SetString(PyExc_SystemError, message)`, where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

Issuing warnings

Use these functions to issue warnings from C code. They mirror similar functions exported by the Python **`warnings`** module. They normally print a warning message to *sys.stderr*; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case they will raise an exception. It is also possible that the functions raise an exception because of a problem with the warning machinery. The return value is `0` if no exception is raised, or `-1` if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, **`Py_DECREF()`** owned references and return an error value).

int PyErr_WarnEx(PyObject *category, const char *message, Py_ssize_t stack_level)

Part of the Stable ABI.
Issue a warning message. The *category* argument is a warning category (see below) or `NULL`; the *message* argument is a UTF-8 encoded string. *stack_level* is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A *stack_level* of 1 is the function calling **`PyErr_WarnEx()`**, 2 is the function above that, and so forth.

Warning categories must be subclasses of **`PyExc_Warning`**; **`PyExc_Warning`** is a subclass of **`PyExc_Exception`**; the default warning category is **`PyExc_RuntimeWarning`**. The standard Python warning categories are available as global variables whose names are enumerated at Standard Warning Categories.

For information about warning control, see the documentation for the **warnings** module and the **-W** option in the command line documentation. There is no C API for warning control.

int PyErr_WarnExplicitObject(PyObject *category, PyObject *message, PyObject *filename, int lineno, PyObject *module, PyObject *registry)

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function **warnings.warn_explicit()**; see there for more information. The *module* and *registry* arguments may be set to `NULL` to get the default effect described there.

New in version 3.4.

int PyErr_WarnExplicit(PyObject *category, const char *message, const char *filename, int lineno, const char *module, PyObject *registry)

Part of the Stable ABI.
Similar to **PyErr_WarnExplicitObject()** except that *message* and *module* are UTF-8 encoded strings, and *filename* is decoded from the filesystem encoding and error handler.

int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level, const char *format, ...)

Part of the Stable ABI.
Function similar to **PyErr_WarnEx()**, but use **PyUnicode_FromFormat()** to format the warning message. *format* is an ASCII-encoded string.

New in version 3.2.

int PyErr_ResourceWarning(PyObject *source, Py_ssize_t stack_level, const char *format, ...)

Part of the Stable ABI since version 3.6.

Function similar to **PyErr_WarnFormat()**, but *category* is **ResourceWarning** and it passes *source* to **warnings.WarningMessage()**.

New in version 3.6.

Querying the error indicator

PyObject *PyErr_Occurred()

Return value: Borrowed reference. Part of the Stable ABI.
Test whether the error indicator is set. If set, return the exception *type* (the first argument to the last call to one of the `PyErr_Set*` functions or to **PyErr_Restore()**). If not set, return `NULL`. You do not own a reference to the return value, so you do not need to **Py_DECREF()** it.

The caller must hold the GIL.

Note

Do not compare the return value to a specific exception; use **PyErr_ExceptionMatches()** instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

int PyErr_ExceptionMatches(PyObject *exc)

Part of the Stable ABI.
Equivalent to `PyErr_GivenExceptionMatches(PyErr_Occurred(), exc)`. This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

int PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)

Part of the Stable ABI.

Return true if the *given* exception matches the exception type in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exception types in the tuple (and recursively in subtuples) are searched for a match.

void PyErr_Fetch(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)

Part of the Stable ABI.
Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to `NULL`. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be `NULL` even when the type object is not.

Note

This function is normally only used by code that needs to catch exceptions or by code that needs to save and restore the error indicator temporarily, e.g.:

```
{
    PyObject *type, *value, *traceback;
    PyErr_Fetch(&type, &value, &traceback);

    /* ... code that might produce other errors ...

    PyErr_Restore(type, value, traceback);
}
```

void PyErr_Restore(PyObject *type, PyObject *value, PyObject *traceback)

Part of the Stable ABI.
Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are `NULL`, the error indicator is cleared. Do not pass a `NULL` type

and non-`NULL` value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.)

Note

This function is normally only used by code that needs to save and restore the error indicator temporarily. Use **`PyErr_Fetch()`** to save the current error indicator.

void PyErr_NormalizeException(PyObject **exc, PyObject **val, PyObject **tb)

Part of the Stable ABI.
Under certain circumstances, the values returned by **`PyErr_Fetch()`** below can be "unnormalized", meaning that `*exc` is a class object but `*val` is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

Note

This function *does not* implicitly set the `__traceback__` attribute on the exception value. If setting the traceback appropriately is desired, the following additional snippet is needed:

```
if (tb != NULL) {
  PyException_SetTraceback(val, tb);
}
```

PyObject *PyErr_GetHandledException(void)

Part of the Stable ABI since version 3.11.
Retrieve the active exception instance, as would be returned by **`sys.exception()`**. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns a new reference to the exception or `NULL`. Does not modify the interpreter's exception state.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_SetHandledException()`** to restore or clear the exception state.

New in version 3.11.

void PyErr_SetHandledException(PyObject *exc)

Part of the Stable ABI since version 3.11.
Set the active exception, as known from `sys.exception()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. To clear the exception state, pass `NULL`.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_GetHandledException()`** to get the exception state.

New in version 3.11.

void PyErr_GetExcInfo(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)

Part of the Stable ABI since version 3.7.
Retrieve the old-style representation of the exception info, as

known from **sys.exc_info()**. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns new references for the three objects, any of which may be `NULL`. Does not modify the exception info state. This function is kept for backwards compatibility. Prefer using **PyErr_GetHandledException()**.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **PyErr_SetExcInfo()** to restore or clear the exception state.

New in version 3.3.

void PyErr_SetExcInfo(PyObject *type, PyObject *value, PyObject *traceback)

Part of the Stable ABI since version 3.7.
Set the exception info, as known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. This function steals the references of the arguments. To clear the exception state, pass `NULL` for all three arguments. This function is kept for backwards compatibility. Prefer using **PyErr_SetHandledException()**.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **PyErr_GetExcInfo()** to read the exception state.

New in version 3.3.

Changed in version 3.11: The `type` and `traceback` arguments are no longer used and can be NULL. The

interpreter now derives them from the exception instance (the `value` argument). The function still steals references of all three arguments.

Signal Handling

int PyErr_CheckSignals()

Part of the Stable ABI.
This function interacts with Python's signal handling.

If the function is called from the main thread and under the main Python interpreter, it checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the **`signal`** module is supported, this can invoke a signal handler written in Python.

The function attempts to handle all pending signals, and then returns `0`. However, if a Python signal handler raises an exception, the error indicator is set and the function returns `-1` immediately (such that other pending signals may not have been handled yet: they will be on the next **`PyErr_CheckSignals()`** invocation).

If the function is called from a non-main thread, or under a non-main Python interpreter, it does nothing and returns `0`.

This function can be called by long-running C code that wants to be interruptible by user requests (such as by pressing Ctrl-C).

Note

The default Python signal handler for **`SIGINT`** raises the **`KeyboardInterrupt`** exception.

void PyErr_SetInterrupt()

Part of the Stable ABI.
Simulate the effect of a **`SIGINT`** signal arriving. This is

equivalent to `PyErr_SetInterruptEx(SIGINT)`.

Note

This function is async-signal-safe. It can be called without the GIL and from a C signal handler.

int PyErr_SetInterruptEx(int signum)

Part of the Stable ABI since version 3.10.
Simulate the effect of a signal arriving. The next time **`PyErr_CheckSignals()`** is called, the Python signal handler for the given signal number will be called.

This function can be called by C code that sets up its own signal handling and wants Python signal handlers to be invoked as expected when an interruption is requested (for example when the user presses Ctrl-C to interrupt an operation).

If the given signal isn't handled by Python (it was set to **`signal.SIG_DFL`** or **`signal.SIG_IGN`**), it will be ignored.

If *signum* is outside of the allowed range of signal numbers, `-1` is returned. Otherwise, `0` is returned. The error indicator is never changed by this function.

Note

This function is async-signal-safe. It can be called without the GIL and from a C signal handler.

New in version 3.10.

int PySignal_SetWakeupFd(int fd)

This utility function specifies a file descriptor to which the signal number is written as a single byte whenever a signal is received. *fd* must be non-blocking. It returns the previous such file descriptor.

The value `-1` disables the feature; this is the initial state. This is equivalent to **`signal.set_wakeup_fd()`** in Python, but without any error checking. *fd* should be a valid file descriptor. The function should only be called from the main thread.

Changed in version 3.5: On Windows, the function now also supports socket handles.

Exception Classes

PyObject *PyErr_NewException(const char *name, PyObject *base, PyObject *dict)

Return value: New reference. Part of the Stable ABI.
This utility function creates and returns a new exception class. The *name* argument must be the name of the new exception, a C string of the form `module.classname`. The *base* and *dict* arguments are normally `NULL`. This creates a class object derived from **`Exception`** (accessible in C as **`PyExc_Exception`**).

The **`__module__`** attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The *dict* argument can be used to specify a dictionary of class variables and methods.

PyObject *PyErr_NewExceptionWithDoc(const char *name, const char *doc, PyObject *base, PyObject *dict)

Return value: New reference. Part of the Stable ABI.
Same as **`PyErr_NewException()`**, except that the new exception class can easily be given a docstring: If *doc* is non-`NULL`, it will be used as the docstring for the exception class.

New in version 3.2.

Exception Objects

PyObject *PyException_GetTraceback(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the traceback associated with the exception as a new reference, as accessible from Python through **__traceback__**. If there is no traceback associated, this returns `NULL`.

int PyException_SetTraceback(PyObject *ex, PyObject *tb)

Part of the Stable ABI.
Set the traceback associated with the exception to *tb*. Use `Py_None` to clear it.

PyObject *PyException_GetContext(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the context (another exception instance during whose handling *ex* was raised) associated with the exception as a new reference, as accessible from Python through **__context__**. If there is no context associated, this returns `NULL`.

void PyException_SetContext(PyObject *ex, PyObject *ctx)

Part of the Stable ABI.
Set the context associated with the exception to *ctx*. Use `NULL` to clear it. There is no type check to make sure that *ctx* is an exception instance. This steals a reference to *ctx*.

PyObject *PyException_GetCause(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the cause (either an exception instance, or **None**, set by `raise ... from ...`) associated with the exception as a new reference, as accessible from Python through **__cause__**.

void PyException_SetCause(PyObject *ex, PyObject *cause)

Part of the Stable ABI.
Set the cause associated with the exception to *cause*. Use `NULL` to clear it. There is no type check to make sure that *cause* is either an exception instance or **`None`**. This steals a reference to *cause*.

`__suppress_context__` is implicitly set to `True` by this function.

Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

PyObject *PyUnicodeDecodeError_Create(const char *encoding, const char *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)

Return value: New reference. Part of the Stable ABI.
Create a **`UnicodeDecodeError`** object with the attributes *encoding*, *object*, *length*, *start*, *end* and *reason*. *encoding* and *reason* are UTF-8 encoded strings.

PyObject *PyUnicodeDecodeError_GetEncoding(PyObject *exc)
PyObject *PyUnicodeEncodeError_GetEncoding(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Return the *encoding* attribute of the given exception object.

PyObject *PyUnicodeDecodeError_GetObject(PyObject *exc)
PyObject *PyUnicodeEncodeError_GetObject(PyObject *exc)
PyObject *PyUnicodeTranslateError_GetObject(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Return the *object* attribute of the given exception object.

int PyUnicodeDecodeError_GetStart(PyObject *exc, Py_ssize_t *start)
int PyUnicodeEncodeError_GetStart(PyObject *exc, Py_ssize_t

*start)

int PyUnicodeTranslateError_GetStart(PyObject *exc, Py_ssize_t *start)

Part of the Stable ABI.
Get the *start* attribute of the given exception object and place it into **start*. *start* must not be `NULL`. Return `0` on success, `-1` on failure.

int PyUnicodeDecodeError_SetStart(PyObject *exc, Py_ssize_t start)

int PyUnicodeEncodeError_SetStart(PyObject *exc, Py_ssize_t start)

int PyUnicodeTranslateError_SetStart(PyObject *exc, Py_ssize_t start)

Part of the Stable ABI.
Set the *start* attribute of the given exception object to *start*. Return `0` on success, `-1` on failure.

int PyUnicodeDecodeError_GetEnd(PyObject *exc, Py_ssize_t *end)

int PyUnicodeEncodeError_GetEnd(PyObject *exc, Py_ssize_t *end)

int PyUnicodeTranslateError_GetEnd(PyObject *exc, Py_ssize_t *end)

Part of the Stable ABI.
Get the *end* attribute of the given exception object and place it into **end*. *end* must not be `NULL`. Return `0` on success, `-1` on failure.

int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)

int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)

int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)

Part of the Stable ABI.
Set the *end* attribute of the given exception object to *end*. Return `0` on success, `-1` on failure.

PyObject *PyUnicodeDecodeError_GetReason(PyObject *exc)

PyObject *PyUnicodeEncodeError_GetReason(PyObject *exc)

PyObject *PyUnicodeTranslateError_GetReason(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Return the *reason* attribute of the given exception object.

int PyUnicodeDecodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeEncodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeTranslateError_SetReason(PyObject *exc, const char *reason)

Part of the Stable ABI.
Set the *reason* attribute of the given exception object to *reason*. Return `0` on success, `-1` on failure.

Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically). They are also not needed for *tp_call* implementations because the call protocol takes care of recursion handling.

int Py_EnterRecursiveCall(const char *where)

Part of the Stable ABI since version 3.9.
Marks a point where a recursive C-level call is about to be performed.

If **`USE_STACKCHECK`** is defined, this function checks if the OS stack overflowed using **`PyOS_CheckStack()`**. In this is the case, it sets a **`MemoryError`** and returns a nonzero value.

The function then checks if the recursion limit is reached. If this is the case, a **`RecursionError`** is set and a nonzero value is returned. Otherwise, zero is returned.

where should be a UTF-8 encoded string such as `" in instance check"` to be concatenated to the

RecursionError message caused by the recursion depth limit.

Changed in version 3.9: This function is now also available in the limited API.

void Py_LeaveRecursiveCall(void)

Part of the Stable ABI since version 3.9.
Ends a **Py_EnterRecursiveCall()**. Must be called once for each *successful* invocation of **Py_EnterRecursiveCall()**.

Changed in version 3.9: This function is now also available in the limited API.

Properly implementing **tp_repr** for container types requires special recursion handling. In addition to protecting the stack, **tp_repr** also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to **reprlib.recursive_repr()**.

int Py_ReprEnter(PyObject *object)

Part of the Stable ABI.
Called at the beginning of the **tp_repr** implementation to detect cycles.

If the object has already been processed, the function returns a positive integer. In that case the **tp_repr** implementation should return a string object indicating a cycle. As examples, **dict** objects return `{...}` and **list** objects return `[...]`.

The function will return a negative integer if the recursion limit is reached. In that case the **tp_repr** implementation should typically return `NULL`.

Otherwise, the function returns zero and the **tp_repr** implementation can continue normally.

void Py_ReprLeave(PyObject *object)

Part of the Stable ABI.
Ends a `Py_ReprEnter()`. Must be called once for each invocation of `Py_ReprEnter()` that returns zero.

Standard Exceptions

All standard Python exceptions are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type PyObject*; they are all class objects. For completeness, here are all the variables:

C Name	Python Name
PyExc_BaseException	BaseException
PyExc_Exception	Exception
PyExc_ArithmeticError	ArithmeticError
PyExc_AssertionError	AssertionError
PyExc_AttributeError	AttributeError
PyExc_BlockingIOError	BlockingIOError
PyExc_BrokenPipeError	BrokenPipeError
PyExc_BufferError	BufferError
PyExc_ChildProcessError	ChildProcessError
PyExc_ConnectionAbortedError	ConnectionAbortedError
PyExc_ConnectionError	ConnectionError
PyExc_ConnectionRefusedError	ConnectionRefusedError
PyExc_ConnectionResetError	ConnectionResetError
PyExc_EOFError	EOFError
PyExc_FileExistsError	FileExistsError
PyExc_FileNotFoundError	FileNotFoundError
PyExc_FloatingPointError	FloatingPointError
PyExc_GeneratorExit	GeneratorExit
PyExc_ImportError	ImportError
PyExc_IndentationError	IndentationError
PyExc_IndexError	IndexError
PyExc_InterruptedError	InterruptedError
PyExc_IsADirectoryError	IsADirectoryError
PyExc_KeyError	KeyError
PyExc_KeyboardInterrupt	KeyboardInterrupt
PyExc_LookupError	LookupError

PyExc_MemoryError
PyExc_ModuleNotFoundError
PyExc_NameError
PyExc_NotADirectoryError
PyExc_NotImplementedError
PyExc_OSError
PyExc_OverflowError
PyExc_PermissionError
PyExc_ProcessLookupError
PyExc_RecursionError
PyExc_ReferenceError
PyExc_RuntimeError
PyExc_StopAsyncIteration
PyExc_StopIteration
PyExc_SyntaxError
PyExc_SystemError
PyExc_SystemExit
PyExc_TabError
PyExc_TimeoutError
PyExc_TypeError
PyExc_UnboundLocalError
PyExc_UnicodeDecodeError
PyExc_UnicodeEncodeError
PyExc_UnicodeError
PyExc_UnicodeTranslateError
PyExc_ValueError
PyExc_ZeroDivisionError

New in version 3.3: **PyExc_BlockingIOError**, **PyExc_BrokenPipeError**, **PyExc_ChildProcessError**, **PyExc_ConnectionError**, **PyExc_ConnectionAbortedError**, **PyExc_ConnectionRefusedError**, **PyExc_ConnectionResetError**, **PyExc_FileExistsError**, **PyExc_FileNotFoundError**, **PyExc_InterruptedError**, **PyExc_IsADirectoryError**, **PyExc_NotADirectoryError**, **PyExc_PermissionError**, **PyExc_ProcessLookupError** and **PyExc_TimeoutError** were introduced following **PEP 3151** [https://peps.python.org/pep-3151/].

New in version 3.5: **PyExc_StopAsyncIteration** and **PyExc_RecursionError**.

New in version 3.6: **PyExc_ModuleNotFoundError**.

These are compatibility aliases to **PyExc_OSError**:

C Name	Notes
PyExc_EnvironmentError	
PyExc_IOError	
PyExc_WindowsError	2

Changed in version 3.3: These aliases used to be separate exception types.

Notes:

1(*1*,*2*,*3*,*4*,*5*)
This is a base class for other standard exceptions.

2
Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

Standard Warning Categories

All standard Python warning categories are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type PyObject*; they are all class objects. For completeness, here are all the variables:

C Name	Notes
PyExc_Warning	3
PyExc_BytesWarning	
PyExc_DeprecationWarning	
PyExc_FutureWarning	
PyExc_ImportWarning	
PyExc_PendingDeprecationWarning	
PyExc_ResourceWarning	
PyExc_RuntimeWarning	
PyExc_SyntaxWarning	
PyExc_UnicodeWarning	
PyExc_UserWarning	

PyExc_SyntaxWarning	
PyExc_UnicodeWarning	
PyExc_UserWarning	

New in version 3.2: **PyExc_ResourceWarning**.

Notes:

3

This is a base class for other standard warning categories.

Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

- Operating System Utilities
- System Functions
- Process Control
- Importing Modules
- Data marshalling support
- Parsing arguments and building values
    - Parsing arguments
        - Strings and buffers
        - Numbers
        - Other objects
        - API Functions
    - Building values
- String conversion and formatting
- Reflection
- Codec registry and support functions
    - Codec lookup API
    - Registry API for Unicode encoding error handlers

Operating System Utilities

PyObject *PyOS_FSPath(PyObject *path)

Return value: New reference. Part of the Stable ABI since version 3.6.
Return the file system representation for *path*. If the object is a **str** or **bytes** object, then its reference count is incremented. If the object implements the **os.PathLike** interface, then **__fspath__()** is returned as long as it is a **str** or **bytes** object. Otherwise **TypeError** is raised and `NULL` is returned.

New in version 3.6.

int Py_FdIsInteractive(FILE *fp, const char *filename)

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which `isatty(fileno(fp))` is true. If the global flag **Py_InteractiveFlag** is true, this function also returns true if the *filename* pointer is `NULL` or if the name is equal to one of the strings `'<stdin>'` or `'???'`.

void PyOS_BeforeFork()

Part of the Stable ABI on platforms with fork() since version 3.7.
Function to prepare some internal state before a process fork. This should be called before calling **fork()** or any similar function that clones the current process. Only available on systems where **fork()** is defined.

Warning

The C **fork()** call should only be made from the "main" thread (of the "main" interpreter). The same is true for `PyOS_BeforeFork()`.

New in version 3.7.

void PyOS_AfterFork_Parent()

Part of the Stable ABI on platforms with fork() since version 3.7. Function to update some internal state after a process fork. This should be called from the parent process after calling **fork()** or any similar function that clones the current process, regardless of whether process cloning was successful. Only available on systems where **fork()** is defined.

Warning

The C **fork()** call should only be made from the "main" thread (of the "main" interpreter). The same is true for `PyOS_AfterFork_Parent()`.

New in version 3.7.

void PyOS_AfterFork_Child()

Part of the Stable ABI on platforms with fork() since version 3.7. Function to update internal interpreter state after a process fork. This must be called from the child process after calling **fork()**, or any similar function that clones the current process, if there is any chance the process will call back into the Python interpreter. Only available on systems where **fork()** is defined.

Warning

The C **fork()** call should only be made from the "main" thread (of the "main" interpreter). The same is true for `PyOS_AfterFork_Child()`.

New in version 3.7.

See also

os.register_at_fork() allows registering custom Python functions to be called by **PyOS_BeforeFork()**,

PyOS_AfterFork_Parent() and **PyOS_AfterFork_Child()**.

void PyOS_AfterFork()

Part of the Stable ABI on platforms with fork().
Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

Deprecated since version 3.7: This function is superseded by **PyOS_AfterFork_Child()**.

int PyOS_CheckStack()

Part of the Stable ABI on platforms with USE_STACKCHECK since version 3.7.
Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when **USE_STACKCHECK** is defined (currently on certain versions of Windows using the Microsoft Visual C++ compiler). **USE_STACKCHECK** will be defined automatically; you should never change the definition in your own code.

PyOS_sighandler_t PyOS_getsig(int i)

Part of the Stable ABI.
Return the current signal handler for signal *i*. This is a thin wrapper around either **sigaction()** or **signal()**. Do not call those functions directly! **PyOS_sighandler_t** is a typedef alias for void (*)(int).

PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)

Part of the Stable ABI.
Set the signal handler for signal *i* to be *h*; return the old signal handler. This is a thin wrapper around either **sigaction()** or **signal()**. Do not call those functions directly! **PyOS_sighandler_t** is a typedef alias for void (*)(int).

wchar_t *Py_DecodeLocale(const char *arg, size_t *size)

Part of the Stable ABI since version 3.7.

Warning

This function should not be called directly: use the **PyConfig** API with the **PyConfig_SetBytesString()** function which ensures that Python is preinitialized.

This function must not be called before Python is preinitialized and so that the LC_CTYPE locale is properly configured: see the **Py_PreInitialize()** function.

Decode a byte string from the filesystem encoding and error handler. If the error handler is surrogateescape error handler, undecodable bytes are decoded as characters in range U+DC80..U+DCFF; and if a byte sequence can be decoded as a surrogate character, the bytes are escaped using the surrogateescape error handler instead of decoding them.

Return a pointer to a newly allocated wide character string, use **PyMem_RawFree()** to free the memory. If size is not `NULL`, write the number of wide characters excluding the null character into `*size`

Return `NULL` on decoding error or memory allocation error. If *size* is not `NULL`, `*size` is set to `(size_t)-1` on memory error or set to `(size_t)-2` on decoding error.

The filesystem encoding and error handler are selected by **PyConfig_Read()**: see **filesystem_encoding** and **filesystem_errors** members of **PyConfig**.

Decoding errors should never happen, unless there is a bug in the C library.

Use the **Py_EncodeLocale()** function to encode the character string back to a byte string.

See also

The **PyUnicode_DecodeFSDefaultAndSize()** and **PyUnicode_DecodeLocaleAndSize()** functions.

New in version 3.5.

Changed in version 3.7: The function now uses the UTF-8 encoding in the Python UTF-8 Mode.

Changed in version 3.8: The function now uses the UTF-8 encoding on Windows if **Py_LegacyWindowsFSEncodingFlag** is zero;

char *Py_EncodeLocale(const wchar_t *text, size_t *error_pos)

Part of the Stable ABI since version 3.7.
Encode a wide character string to the filesystem encoding and error handler. If the error handler is surrogateescape error handler, surrogate characters in the range U+DC80..U+DCFF are converted to bytes 0x80..0xFF.

Return a pointer to a newly allocated byte string, use **PyMem_Free()** to free the memory. Return `NULL` on encoding error or memory allocation error.

If error_pos is not `NULL`, `*error_pos` is set to `(size_t)-1` on success, or set to the index of the invalid character on encoding error.

The filesystem encoding and error handler are selected by **PyConfig_Read()**: see **filesystem_encoding** and **filesystem_errors** members of **PyConfig**.

Use the **Py_DecodeLocale()** function to decode the bytes string back to a wide character string.

Warning

This function must not be called before Python is preinitialized and so that the LC_CTYPE locale is properly configured: see the **Py_PreInitialize()** function.

See also

The **PyUnicode_EncodeFSDefault()** and **PyUnicode_EncodeLocale()** functions.

New in version 3.5.

Changed in version 3.7: The function now uses the UTF-8 encoding in the Python UTF-8 Mode.

Changed in version 3.8: The function now uses the UTF-8 encoding on Windows if **Py_LegacyWindowsFSEncodingFlag** is zero.

System Functions

These are utility functions that make functionality from the **sys** module accessible to C code. They all work with the current interpreter thread's **sys** module's dict, which is contained in the internal thread state structure.

PyObject *PySys_GetObject(const char *name)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object *name* from the **sys** module or `NULL` if it does not exist, without setting an exception.

int PySys_SetObject(const char *name, PyObject *v)

Part of the Stable ABI.
Set *name* in the **sys** module to *v* unless *v* is `NULL`, in which case *name* is deleted from the sys module. Returns `0` on success, `-1` on error.

void PySys_ResetWarnOptions()

Part of the Stable ABI.
Reset **sys.warnoptions** to an empty list. This function may be called prior to **Py_Initialize()**.

void PySys_AddWarnOption(const wchar_t *s)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.warnoptions** should be used instead, see Python Initialization Configuration.

Append *s* to **sys.warnoptions**. This function must be called prior to **Py_Initialize()** in order to affect the warnings filter list.

Deprecated since version 3.11.

void PySys_AddWarnOptionUnicode(PyObject *unicode)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.warnoptions** should be used instead, see Python Initialization Configuration.

Append *unicode* to **sys.warnoptions**.

Note: this function is not currently usable from outside the CPython implementation, as it must be called prior to the implicit import of **warnings** in **Py_Initialize()** to be effective, but can't be called until enough of the runtime has been initialized to permit the creation of Unicode objects.

Deprecated since version 3.11.

void PySys_SetPath(const wchar_t *path)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.module_search_paths** and **PyConfig.module_search_paths_set** should be used instead, see Python Initialization Configuration.

Set **sys.path** to a list object of paths found in *path* which should be a list of paths separated with the platform's search path delimiter (`:` on Unix, `;` on Windows).

Deprecated since version 3.11.

void PySys_WriteStdout(const char *format, ...)

Part of the Stable ABI.
Write the output string described by *format* to **sys.stdout**. No exceptions are raised, even if truncation occurs (see below).

format should limit the total size of the formatted output string to 1000 bytes or less – after 1000 bytes, the output string is truncated. In particular, this means that no unrestricted "%s" formats should occur; these should be limited using "%.<N>s" where <N> is a decimal number calculated so that <N> plus the maximum size of other formatted text does not exceed 1000 bytes. Also watch out for "%f", which can print hundreds of digits for very large numbers.

If a problem occurs, or **sys.stdout** is unset, the formatted message is written to the real (C level) *stdout*.

void PySys_WriteStderr(const char *format, ...)

Part of the Stable ABI.
As **PySys_WriteStdout()**, but write to **sys.stderr** or *stderr* instead.

void PySys_FormatStdout(const char *format, ...)

Part of the Stable ABI.
Function similar to PySys_WriteStdout() but format the message using **PyUnicode_FromFormatV()** and don't truncate the message to an arbitrary length.

New in version 3.2.

void PySys_FormatStderr(const char *format, ...)

Part of the Stable ABI.
As **PySys_FormatStdout()**, but write to **sys.stderr** or *stderr* instead.

New in version 3.2.

void PySys_AddXOption(const wchar_t *s)

Part of the Stable ABI since version 3.7.
This API is kept for backward compatibility: setting **PyConfig.xoptions** should be used instead, see Python Initialization Configuration.

Parse *s* as a set of **-X** options and add them to the current options mapping as returned by **PySys_GetXOptions()**. This function may be called prior to **Py_Initialize()**.

New in version 3.2.

Deprecated since version 3.11.

PyObject *PySys_GetXOptions()

Return value: Borrowed reference. Part of the Stable ABI since version 3.7.
Return the current dictionary of **-X** options, similarly to **sys._xoptions**. On error, `NULL` is returned and an exception is set.

New in version 3.2.

int PySys_Audit(const char *event, const char *format, ...)

Raise an auditing event with any active hooks. Return zero for success and non-zero with an exception set on failure.

If any hooks have been added, *format* and other arguments will be used to construct a tuple to pass. Apart from `N`, the same format characters as used in **Py_BuildValue()** are available. If the built value is not a tuple, it will be added into a single-element tuple. (The `N` format option consumes a reference, but since there is no way to know whether arguments to this function will be consumed, using it may cause reference leaks.)

Note that `#` format characters should always be treated as **Py_ssize_t**, regardless of whether `PY_SSIZE_T_CLEAN` was defined.

sys.audit() performs the same function from Python code.

New in version 3.8.

Changed in version 3.8.2: Require **Py_ssize_t** for # format characters. Previously, an unavoidable deprecation warning was raised.

int PySys_AddAuditHook(Py_AuditHookFunction hook, void *userData)

Append the callable *hook* to the list of active auditing hooks. Return zero on success and non-zero on failure. If the runtime has been initialized, also set an error on failure. Hooks added through this API are called for all interpreters created by the runtime.

The *userData* pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

This function is safe to call before **Py_Initialize()**. When called after runtime initialization, existing audit hooks are notified and may silently abort the operation by raising an error subclassed from **Exception** (other errors will not be silenced).

The hook function is of type int (*)(const char *event, PyObject *args, void *userData), where *args* is guaranteed to be a **PyTupleObject**. The hook function is always called with the GIL held by the Python interpreter that raised the event.

See **PEP 578** [https://peps.python.org/pep-0578/] for a detailed description of auditing. Functions in the runtime and standard library that raise events are listed in the audit events table. Details are in each function's documentation.

If the interpreter is initialized, this function raises a auditing event `sys.addaudithook` with no arguments. If any existing hooks raise an exception derived from **Exception**,

the new hook will not be added and the exception is cleared. As a result, callers cannot assume that their hook has been added unless they control all existing hooks.

New in version 3.8.

Process Control

void Py_FatalError(const char *message)

Part of the Stable ABI.
Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function **`abort()`** is called which will attempt to produce a `core` file.

The `Py_FatalError()` function is replaced with a macro which logs automatically the name of the current function, unless the `Py_LIMITED_API` macro is defined.

Changed in version 3.9: Log the function name automatically.

void Py_Exit(int status)

Part of the Stable ABI.
Exit the current process. This calls **`Py_FinalizeEx()`** and then calls the standard C library function `exit(status)`. If **`Py_FinalizeEx()`** indicates an error, the exit status is set to 120.

Changed in version 3.6: Errors from finalization no longer ignored.

int Py_AtExit(void (*func)())

Part of the Stable ABI.
Register a cleanup function to be called by **`Py_FinalizeEx()`**. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, **`Py_AtExit()`** returns `0`; on failure, it returns `-1`. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by *func*.

Importing Modules

PyObject *PyImport_ImportModule(const char *name)

Return value: New reference. Part of the Stable ABI.
This is a simplified interface to **`PyImport_ImportModuleEx()`** below, leaving the *globals* and *locals* arguments set to `NULL` and *level* set to 0. When the *name* argument contains a dot (when it specifies a submodule of a package), the *fromlist* argument is set to the list `['*']` so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when *name* in fact specifies a subpackage instead of a submodule: the submodules specified in the package's `__all__` variable are loaded.) Return a new reference to the imported module, or `NULL` with an exception set on failure. A failing import of a module doesn't leave the module in **`sys.modules`**.

This function always uses absolute imports.

PyObject *PyImport_ImportModuleNoBlock(const char *name)

Return value: New reference. Part of the Stable ABI.
This function is a deprecated alias of **`PyImport_ImportModule()`**.

Changed in version 3.3: This function used to fail immediately when the import lock was held by another thread. In Python 3.3 though, the locking scheme switched to per-module locks for most purposes, so this function's special behaviour isn't needed anymore.

PyObject *PyImport_ImportModuleEx(const char *name, PyObject *globals, PyObject *locals, PyObject *fromlist)

Return value: New reference.

Import a module. This is best described by referring to the built-in Python function **`__import__()`**.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for **`__import__()`**, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

Failing imports remove incomplete module objects, like with **`PyImport_ImportModule()`**.

PyObject *PyImport_ImportModuleLevelObject(PyObject *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Return value: New reference. Part of the Stable ABI since version 3.7.
Import a module. This is best described by referring to the built-in Python function **`__import__()`**, as the standard **`__import__()`** function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for **`__import__()`**, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

New in version 3.3.

PyObject *PyImport_ImportModuleLevel(const char *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Return value: New reference. Part of the Stable ABI.
Similar to **`PyImport_ImportModuleLevelObject()`**, but the name is a UTF-8 encoded string instead of a Unicode object.

Changed in version 3.3: Negative values for *level* are no longer accepted.

PyObject *PyImport_Import(PyObject *name)

Return value: New reference. Part of the Stable ABI.
This is a higher-level interface that calls the current "import hook function" (with an explicit *level* of 0, meaning absolute import). It invokes the **`__import__()`** function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

PyObject *PyImport_ReloadModule(PyObject *m)

Return value: New reference. Part of the Stable ABI.
Reload a module. Return a new reference to the reloaded module, or `NULL` with an exception set on failure (the module still exists in this case).

PyObject *PyImport_AddModuleObject(PyObject *name)

Return value: Borrowed reference. Part of the Stable ABI since version 3.7.
Return the module object corresponding to a module name. The *name* argument may be of the form `package.module`. First check the modules dictionary if there's one there, and if not, create a new one and insert it in the modules dictionary. Return `NULL` with an exception set on failure.

Note

This function does not load or import the module; if the module wasn't already loaded, you will get an empty module object. Use **`PyImport_ImportModule()`** or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.

New in version 3.3.

PyObject *PyImport_AddModule(const char *name)

Return value: Borrowed reference. Part of the Stable ABI.

Similar to **PyImport_AddModuleObject()**, but the name is a UTF-8 encoded string instead of a Unicode object.

PyObject *PyImport_ExecCodeModule(const char *name, PyObject *co)

Return value: New reference. Part of the Stable ABI.
Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function **compile()**, load the module. Return a new reference to the module object, or `NULL` with an exception set if an error occurred. *name* is removed from **sys.modules** in error cases, even if *name* was already in **sys.modules** on entry to **PyImport_ExecCodeModule()**. Leaving incompletely initialized modules in **sys.modules** is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author's intents) state.

The module's **__spec__** and **__loader__** will be set, if not set already, with the appropriate values. The spec's loader will be set to the module's `__loader__` (if set) and to an instance of **SourceFileLoader** otherwise.

The module's **__file__** attribute will be set to the code object's **co_filename**. If applicable, **__cached__** will also be set.

This function will reload the module if it was already imported. See **PyImport_ReloadModule()** for the intended way to reload a module.

If *name* points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

See also **PyImport_ExecCodeModuleEx()** and **PyImport_ExecCodeModuleWithPathnames()**.

PyObject *PyImport_ExecCodeModuleEx(const char *name,

PyObject *co, const char *pathname)

Return value: New reference. Part of the Stable ABI.
Like **PyImport_ExecCodeModule()**, but the **__file__** attribute of the module object is set to *pathname* if it is non-NULL.

See also **PyImport_ExecCodeModuleWithPathnames()**.

PyObject *PyImport_ExecCodeModuleObject(PyObject *name, PyObject *co, PyObject *pathname, PyObject *cpathname)

Return value: New reference. Part of the Stable ABI since version 3.7.
Like **PyImport_ExecCodeModuleEx()**, but the **__cached__** attribute of the module object is set to *cpathname* if it is non-NULL. Of the three functions, this is the preferred one to use.

New in version 3.3.

PyObject *PyImport_ExecCodeModuleWithPathnames(const char *name, PyObject *co, const char *pathname, const char *cpathname)

Return value: New reference. Part of the Stable ABI.
Like **PyImport_ExecCodeModuleObject()**, but *name*, *pathname* and *cpathname* are UTF-8 encoded strings. Attempts are also made to figure out what the value for *pathname* should be from *cpathname* if the former is set to NULL.

New in version 3.2.

Changed in version 3.3: Uses **imp.source_from_cache()** in calculating the source path if only the bytecode path is provided.

long PyImport_GetMagicNumber()

Part of the Stable ABI.
Return the magic number for Python bytecode files (a.k.a. .pyc file). The magic number should be present in the first

four bytes of the bytecode file, in little-endian byte order. Returns `-1` on error.

Changed in version 3.3: Return value of `-1` upon failure.

const char *PyImport_GetMagicTag()

Part of the Stable ABI.
Return the magic tag string for **PEP 3147** [https://peps.python.org/pep-3147/] format Python bytecode file names. Keep in mind that the value at `sys.implementation.cache_tag` is authoritative and should be used instead of this function.

New in version 3.2.

PyObject *PyImport_GetModuleDict()

Return value: Borrowed reference. Part of the Stable ABI.
Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

PyObject *PyImport_GetModule(PyObject *name)

Return value: New reference. Part of the Stable ABI since version 3.8.
Return the already imported module with the given name. If the module has not been imported yet then returns `NULL` but does not set an error. Returns `NULL` and sets an error if the lookup failed.

New in version 3.7.

PyObject *PyImport_GetImporter(PyObject *path)

Return value: New reference. Part of the Stable ABI.
Return a finder object for a **`sys.path`**/**`pkg.__path__`** item *path*, possibly by fetching it from the **`sys.path_importer_cache`** dict. If it wasn't yet cached, traverse **`sys.path_hooks`** until a hook is found that can handle the path item. Return `None` if no hook could; this

tells our caller that the path based finder could not find a finder for this path item. Cache the result in **sys.path_importer_cache**. Return a new reference to the finder object.

int PyImport_ImportFrozenModuleObject(PyObject *name)

Part of the Stable ABI since version 3.7.
Load a frozen module named *name*. Return `1` for success, `0` if the module is not found, and `-1` with an exception set if the initialization failed. To access the imported module on a successful load, use **PyImport_ImportModule()**. (Note the misnomer — this function would reload the module if it was already imported.)

New in version 3.3.

Changed in version 3.4: The `__file__` attribute is no longer set on the module.

int PyImport_ImportFrozenModule(const char *name)

Part of the Stable ABI.
Similar to **PyImport_ImportFrozenModuleObject()**, but the name is a UTF-8 encoded string instead of a Unicode object.

struct _frozen

This is the structure type definition for frozen module descriptors, as generated by the **freeze** utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:

```
struct _frozen {
    const char *name;
    const unsigned char *code;
    int size;
    bool is_package;
};
```

Changed in version 3.11: The new `is_package` field

indicates whether the module is a package or not. This replaces setting the `size` field to a negative value.

const struct _frozen *PyImport_FrozenModules

This pointer is initialized to point to an array of **`_frozen`** records, terminated by one whose members are all `NULL` or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInittab(const char *name, PyObject *(*initfunc)(void))

Part of the Stable ABI.
Add a single module to the existing table of built-in modules. This is a convenience wrapper around **`PyImport_ExtendInittab()`**, returning `-1` if the table could not be extended. The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted import. This should be called before **`Py_Initialize()`**.

struct _inittab

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. The name is an ASCII encoded string. Programs which embed Python may use an array of these structures in conjunction with **`PyImport_ExtendInittab()`** to provide additional built-in modules. The structure is defined in `Include/import.h` as:

```
struct _inittab {
    const char *name;           /* ASCII encoded st
    PyObject* (*initfunc)(void);
};
```

int PyImport_ExtendInittab(struct _inittab *newtab)

Add a collection of modules to the table of built-in modules.

The *newtab* array must end with a sentinel entry which contains `NULL` for the **`name`** field; failure to provide the sentinel value can result in a memory fault. Returns `0` on success or `-1` if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This must be called before **`Py_Initialize()`**.

If Python is initialized multiple times, **`PyImport_AppendInittab()`** or **`PyImport_ExtendInittab()`** must be called before each Python initialization.

Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the **marshal** module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 shares interned strings in the file, and upon unmarshalling. Version 2 uses a binary format for floating point numbers. `Py_MARSHAL_VERSION` indicates the current file format (currently 2).

void PyMarshal_WriteLongToFile(long value, FILE *file, int version)

Marshal a long integer, *value*, to *file*. This will only write the least-significant 32 bits of *value*; regardless of the size of the native long type. *version* indicates the file format.

void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)

Marshal a Python object, *value*, to *file*. *version* indicates the file format.

PyObject *PyMarshal_WriteObjectToString(PyObject *value, int version)

Return value: New reference.
Return a bytes object containing the marshalled representation of *value*. *version* indicates the file format.

The following functions allow marshalled values to be read back in.

long PyMarshal_ReadLongFromFile(FILE *file)

Return a C long from the data stream in a FILE* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

On error, sets the appropriate exception (**EOFError**) and returns `-1`.

int PyMarshal_ReadShortFromFile(FILE *file)

Return a C short from the data stream in a FILE* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

On error, sets the appropriate exception (**EOFError**) and returns `-1`.

PyObject *PyMarshal_ReadObjectFromFile(FILE *file)

Return value: New reference.
Return a Python object from the data stream in a FILE* opened for reading.

On error, sets the appropriate exception (**EOFError**, **ValueError** or **TypeError**) and returns `NULL`.

PyObject *PyMarshal_ReadLastObjectFromFile(FILE *file)

Return value: New reference.
Return a Python object from the data stream in a FILE* opened for reading. Unlike **PyMarshal_ReadObjectFromFile()**, this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the de-serialization can operate from data in memory rather than reading a byte at a time from the file. Only use these variant if you are certain that you won't be reading anything else from the file.

On error, sets the appropriate exception (**EOFError**, **ValueError** or **TypeError**) and returns `NULL`.

PyObject *PyMarshal_ReadObjectFromString(const char *data, Py_ssize_t len)

Return value: New reference.
Return a Python object from the data stream in a byte buffer containing *len* bytes pointed to by *data*.

On error, sets the appropriate exception (**`EOFError`**, **`ValueError`** or **`TypeError`**) and returns `NULL`.

Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in Extending and Embedding the Python Interpreter.

The first three of these functions described, **`PyArg_ParseTuple()`**, **`PyArg_ParseTupleAndKeywords()`**, and **`PyArg_Parse()`**, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

Strings and buffers

These formats allow accessing an object as a contiguous chunk of memory. You don’t have to provide raw storage for the returned unicode or bytes area.

In general, when a format sets a pointer to a buffer, the buffer is managed by the corresponding Python object, and the buffer shares the lifetime of this object. You won’t have to release any memory yourself. The only exceptions are `es`, `es#`, `et` and `et#`.

However, when a **Py_buffer** structure gets filled, the underlying buffer is locked so that the caller can subsequently use the buffer even inside a **Py_BEGIN_ALLOW_THREADS** block without the risk of mutable data being resized or destroyed. As a result, **you have to call PyBuffer_Release()** after you have finished processing the data (or in any early abort case).

Unless otherwise stated, buffers are not NUL-terminated.

Some formats require a read-only bytes-like object, and set a pointer instead of a buffer structure. They work by checking that the object's **PyBufferProcs.bf_releasebuffer** field is `NULL`, which disallows mutable objects such as **bytearray**.

Note

For all `#` variants of formats (`s#`, `y#`, etc.), the macro **PY_SSIZE_T_CLEAN** must be defined before including `Python.h`. On Python 3.9 and older, the type of the length argument is **Py_ssize_t** if the **PY_SSIZE_T_CLEAN** macro is defined, or int otherwise.

`s` (**str**) [const char *]

Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded null code points; if it does, a **ValueError** exception is raised. Unicode objects are converted to C strings using `'utf-8'` encoding. If this conversion fails, a **UnicodeError** is raised.

Note

This format does not accept bytes-like objects. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the `O&` format with **PyUnicode_FSConverter()** as *converter*.

Changed in version 3.5: Previously, **TypeError** was raised when embedded null code points were encountered in the Python string.

`s*` (**str** or bytes-like object) [Py_buffer]

This format accepts Unicode objects as well as bytes-like objects. It fills a **Py_buffer** structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`s#` (**str**, read-only bytes-like object) [const char *, **Py_ssize_t**]

Like `s*`, except that it doesn't accept mutable objects. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`z` (**str** or `None`) [const char *]

Like `s`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`z*` (**str**, bytes-like object or `None`) [Py_buffer]

Like `s*`, but the Python object may also be `None`, in which case the `buf` member of the **Py_buffer** structure is set to `NULL`.

`z#` (**str**, read-only bytes-like object or `None`) [const char *, **Py_ssize_t**]

Like `s#`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`y` (read-only bytes-like object) [const char *]

This format converts a bytes-like object to a C pointer to a character string; it does not accept Unicode objects. The bytes buffer must not contain embedded null bytes; if it does, a **ValueError** exception is raised.

Changed in version 3.5: Previously, **TypeError** was raised when embedded null bytes were encountered in the bytes

buffer.

`y*` (bytes-like object) [Py_buffer]

This variant on `s*` doesn't accept Unicode objects, only bytes-like objects. **This is the recommended way to accept binary data.**

`y#` (read-only bytes-like object) [const char *, **`Py_ssize_t`**]

This variant on `s#` doesn't accept Unicode objects, only bytes-like objects.

`S` (**`bytes`**) [PyBytesObject *]

Requires that the Python object is a **`bytes`** object, without attempting any conversion. Raises **`TypeError`** if the object is not a bytes object. The C variable may also be declared as PyObject*.

`Y` (**`bytearray`**) [PyByteArrayObject *]

Requires that the Python object is a **`bytearray`** object, without attempting any conversion. Raises **`TypeError`** if the object is not a **`bytearray`** object. The C variable may also be declared as PyObject*.

`u` (**`str`**) [const Py_UNICODE *]

Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of Unicode characters. You must pass the address of a **`Py_UNICODE`** pointer variable, which will be filled with the pointer to an existing Unicode buffer. Please note that the width of a **`Py_UNICODE`** character depends on compilation options (it is either 16 or 32 bits). The Python string must not contain embedded null code points; if it does, a **`ValueError`** exception is raised.

Changed in version 3.5: Previously, **`TypeError`** was raised when embedded null code points were encountered in the Python string.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style **`Py_UNICODE`** API; please migrate to using **`PyUnicode_AsWideCharString()`**.

`u#` (**`str`**) [const Py_UNICODE *, **`Py_ssize_t`**]

This variant on `u` stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length. This variant allows null code points.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style **`Py_UNICODE`** API; please migrate to using **`PyUnicode_AsWideCharString()`**.

`Z` (**`str`** or `None`) [const Py_UNICODE *]

Like `u`, but the Python object may also be `None`, in which case the **`Py_UNICODE`** pointer is set to `NULL`.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style **`Py_UNICODE`** API; please migrate to using **`PyUnicode_AsWideCharString()`**.

`Z#` (**`str`** or `None`) [const Py_UNICODE *, **`Py_ssize_t`**]

Like `u#`, but the Python object may also be `None`, in which case the **`Py_UNICODE`** pointer is set to `NULL`.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style **`Py_UNICODE`** API; please migrate to using **`PyUnicode_AsWideCharString()`**.

`U` (**`str`**) [PyObject *]

Requires that the Python object is a Unicode object, without attempting any conversion. Raises **`TypeError`** if the object is not a Unicode object. The C variable may also be declared as PyObject*.

`w*` (read-write bytes-like object) [Py_buffer]

This format accepts any object which implements the read-write buffer interface. It fills a **`Py_buffer`** structure provided by the caller. The buffer may contain embedded null bytes. The caller have to call **`PyBuffer_Release()`** when it is done with the buffer.

`es` (**`str`**) [const char *encoding, char **buffer]

This variant on `s` is used for encoding Unicode into a

character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust **buffer* to reference the newly allocated storage. The caller is responsible for calling **`PyMem_Free()`** to free the allocated buffer after use.

`et` (**`str`**, **`bytes`** or **`bytearray`**) [const char *encoding, char **buffer]

Same as `es` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

`es#` (**`str`**) [const char *encoding, char **buffer, **`Py_ssize_t`** *buffer_length]

This variant on `s#` is used for encoding Unicode into a character buffer. Unlike the `es` format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding

specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If **buffer* points a `NULL` pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set **buffer* to reference the newly allocated storage. The caller is responsible for calling **`PyMem_Free()`** to free the allocated buffer after usage.

If **buffer* points to a non-`NULL` pointer (an already allocated buffer), **`PyArg_ParseTuple()`** will use this location as the buffer and interpret the initial value of **buffer_length* as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a **`ValueError`** will be set.

In both cases, **buffer_length* is set to the length of the encoded data without the trailing NUL byte.

`et#` (**`str`**, **`bytes`** or **`bytearray`**) [const char *encoding, char **buffer, **`Py_ssize_t`** *buffer_length]

Same as `es#` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

Numbers

`b` (**`int`**) [unsigned char]

Convert a nonnegative Python integer to an unsigned tiny int, stored in a C unsigned char.

`B` (**`int`**) [unsigned char]

Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char.

`h` (**`int`**) [short int]

Convert a Python integer to a C short int.

`H` (**int**) [unsigned short int]
: Convert a Python integer to a C unsigned short int, without overflow checking.

`i` (**int**) [int]
: Convert a Python integer to a plain C int.

`I` (**int**) [unsigned int]
: Convert a Python integer to a C unsigned int, without overflow checking.

`l` (**int**) [long int]
: Convert a Python integer to a C long int.

`k` (**int**) [unsigned long]
: Convert a Python integer to a C unsigned long without overflow checking.

`L` (**int**) [long long]
: Convert a Python integer to a C long long.

`K` (**int**) [unsigned long long]
: Convert a Python integer to a C unsigned long long without overflow checking.

`n` (**int**) [**Py_ssize_t**]
: Convert a Python integer to a C **Py_ssize_t**.

`c` (**bytes** or **bytearray** of length 1) [char]
: Convert a Python byte, represented as a **bytes** or **bytearray** object of length 1, to a C char.

  Changed in version 3.3: Allow **bytearray** objects.

`C` (**str** of length 1) [int]
: Convert a Python character, represented as a **str** object of length 1, to a C int.

`f` (**`float`**) [float]

Convert a Python floating point number to a C float.

`d` (**`float`**) [double]

Convert a Python floating point number to a C double.

`D` (**`complex`**) [Py_complex]

Convert a Python complex number to a C **`Py_complex`** structure.

Other objects

`O` (object) [PyObject *]

Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not `NULL`.

`O!` (object) [*typeobject*, PyObject *]

Store a Python object in a C object pointer. This is similar to `O`, but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type PyObject*) into which the object pointer is stored. If the Python object does not have the required type, **`TypeError`** is raised.

`O&` (object) [*converter*, *anything*]

Convert a Python object to a C variable through a *converter* function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void*. The *converter* function in turn is called as follows:

```
status = converter(object, address);
```

where *object* is the Python object to be converted and *address* is the void* argument that was passed to the `PyArg_Parse*` function. The returned *status* should be `1` for a successful conversion and `0` if the conversion has failed. When the

conversion fails, the *converter* function should raise an exception and leave the content of *address* unmodified.

If the *converter* returns `Py_CLEANUP_SUPPORTED`, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already allocated. In this second call, the *object* parameter will be `NULL`; *address* will have the same value as in the original call.

Changed in version 3.1: `Py_CLEANUP_SUPPORTED` was added.

`p` (**`bool`**) [int]

Tests the value passed in for truth (a boolean **p**redicate) and converts the result to its equivalent C true/false integer value. Sets the int to `1` if the expression was true and `0` if it was false. This accepts any valid Python value. See Truth Value Testing for more information about how Python tests values for truth.

New in version 3.3.

`(items)` (**`tuple`**) [*matching-items*]

The object must be a Python sequence whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

It is possible to pass "long" integers (integers whose value exceeds the platform's **`LONG_MAX`**) however no proper range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C — your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

`|`

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, **PyArg_ParseTuple()** does not touch the contents of the corresponding C variable(s).

`$`

PyArg_ParseTupleAndKeywords() only: Indicates that the remaining arguments in the Python argument list are keyword-only. Currently, all keyword-only arguments must also be optional arguments, so `|` must always be specified before `$` in the format string.

New in version 3.3.

`:`

The list of format units ends here; the string after the colon is used as the function name in error messages (the "associated value" of the exception that **PyArg_ParseTuple()** raises).

`;`

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message. `:` and `;` mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*` functions return true, otherwise they return false and raise an

appropriate exception. When the `PyArg_Parse*` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are left untouched.

API Functions

int PyArg_ParseTuple(PyObject *args, const char *format, ...)

Part of the Stable ABI.
Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int PyArg_VaParse(PyObject *args, const char *format, va_list vargs)

Part of the Stable ABI.
Identical to **`PyArg_ParseTuple()`**, except that it accepts a va_list rather than a variable number of arguments.

int PyArg_ParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...)

Part of the Stable ABI.
Parse the parameters of a function that takes both positional and keyword parameters into local variables. The *keywords* argument is a `NULL`-terminated array of keyword parameter names. Empty names denote positional-only parameters. Returns true on success; on failure, it returns false and raises the appropriate exception.

Changed in version 3.6: Added support for positional-only parameters.

int PyArg_VaParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], va_list vargs)

Part of the Stable ABI.
Identical to **`PyArg_ParseTupleAndKeywords()`**, except that it accepts a va_list rather than a variable number of

arguments.

int PyArg_ValidateKeywordArguments(PyObject*)

Part of the Stable ABI.
Ensure that the keys in the keywords argument dictionary are strings. This is only needed if **PyArg_ParseTupleAndKeywords()** is not used, since the latter already does this check.

New in version 3.2.

int PyArg_Parse(PyObject *args, const char *format, ...)

Part of the Stable ABI.
Function used to deconstruct the argument lists of "old-style" functions — these are functions which use the **METH_OLDARGS** parameter parsing method, which has been removed in Python 3. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.

int PyArg_UnpackTuple(PyObject *args, const char *name, Py_ssize_t min, Py_ssize_t max, ...)

Part of the Stable ABI.
A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be declared as **METH_VARARGS** in function or method tables. The tuple containing the actual parameters should be passed as *args*; it must actually be a tuple. The length of the tuple must be at least *min* and no more than *max*; *min* and *max* may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a PyObject* variable; these will be filled in with the values from *args*; they will contain borrowed references. The variables which correspond to optional parameters not given by *args* will not

be filled in; these should be initialized by the caller. This function returns true on success and false if *args* is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the **_weakref** helper module for weak references:

```
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &objec
        result = PyWeakref_NewRef(object, callback)
    }
    return result;
}
```

The call to **PyArg_UnpackTuple()** in this example is entirely equivalent to this call to **PyArg_ParseTuple()**:

```
PyArg_ParseTuple(args, "O|O:ref", &object, &callbac
```

Building values

PyObject *Py_BuildValue(const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Create a new value based on a format string similar to those accepted by the `PyArg_Parse*` family of functions and a sequence of values. Returns the value or `NULL` in the case of an error; an exception will be raised if `NULL` is returned.

Py_BuildValue() does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it

contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the `s` and `s#` formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by **`Py_BuildValue()`**. In other words, if your code invokes **`malloc()`** and passes the allocated memory to **`Py_BuildValue()`**, your code is responsible for calling **`free()`** for that memory once **`Py_BuildValue()`** returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as `s#`). This can be used to make long format strings a tad more readable.

`s` (**`str`** or `None`) [const char *]
: Convert a null-terminated C string to a Python **`str`** object using `'utf-8'` encoding. If the C string pointer is `NULL`, `None` is used.

`s#` (**`str`** or `None`) [const char *, **`Py_ssize_t`**]
: Convert a C string and its length to a Python **`str`** object using `'utf-8'` encoding. If the C string pointer is `NULL`, the length is ignored and `None` is returned.

`y` (**`bytes`**) [const char *]
: This converts a C string to a Python **`bytes`** object. If the C string pointer is `NULL`, `None` is returned.

`y#` (**`bytes`**) [const char *, **`Py_ssize_t`**]
: This converts a C string and its lengths to a Python object. If the C string pointer is `NULL`, `None` is returned.

`z` (**`str`** or `None`) [const char *]
: Same as `s`.

`z#` (**`str`** or `None`) [const char *, **`Py_ssize_t`**]
: Same as `s#`.

`u` (**`str`**) [const wchar_t *]
: Convert a null-terminated wchar_t buffer of Unicode (UTF-16 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is `NULL`, `None` is returned.

`u#` (**`str`**) [const wchar_t *, **`Py_ssize_t`**]
: Convert a Unicode (UTF-16 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is `NULL`, the length is ignored and `None` is returned.

`U` (**`str`** or `None`) [const char *]
: Same as `s`.

`U#` (**`str`** or `None`) [const char *, **`Py_ssize_t`**]
: Same as `s#`.

`i` (**`int`**) [int]
: Convert a plain C int to a Python integer object.

`b` (**`int`**) [char]
: Convert a plain C char to a Python integer object.

`h` (**`int`**) [short int]
: Convert a plain C short int to a Python integer object.

`l` (**`int`**) [long int]
: Convert a C long int to a Python integer object.

`B` (**`int`**) [unsigned char]
: Convert a C unsigned char to a Python integer object.

`H` (**`int`**) [unsigned short int]
: Convert a C unsigned short int to a Python integer object.

`I` (**`int`**) [unsigned int]
: Convert a C unsigned int to a Python integer object.

`k` (**`int`**) [unsigned long]
: Convert a C unsigned long to a Python integer object.

`L` (**`int`**) [long long]
: Convert a C long long to a Python integer object.

`K` (**`int`**) [unsigned long long]
: Convert a C unsigned long long to a Python integer object.

`n` (**`int`**) [**`Py_ssize_t`**]
: Convert a C **`Py_ssize_t`** to a Python integer.

`c` (**`bytes`** of length 1) [char]
: Convert a C int representing a byte to a Python **`bytes`** object of length 1.

`C` (**`str`** of length 1) [int]
: Convert a C int representing a character to Python **`str`** object of length 1.

`d` (**`float`**) [double]
: Convert a C double to a Python floating point number.

`f` (**`float`**) [float]
: Convert a C float to a Python floating point number.

`D` (**`complex`**) [Py_complex *]
: Convert a C **`Py_complex`** structure to a Python complex number.

`O` (object) [PyObject *]
: Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a `NULL` pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, **`Py_BuildValue()`** will return `NULL` but won't raise an exception. If no exception has been raised yet,

SystemError is set.

`S` (object) [PyObject *]
: Same as `O`.

`N` (object) [PyObject *]
: Same as `O`, except it doesn't increment the reference count on the object. Useful when the object is created by a call to an object constructor in the argument list.

`O&` (object) [*converter*, *anything*]
: Convert *anything* to a Python object through a *converter* function. The function is called with *anything* (which should be compatible with void*) as its argument and should return a "new" Python object, or `NULL` if an error occurred.

`(items)` (**tuple**) [*matching-items*]
: Convert a sequence of C values to a Python tuple with the same number of items.

`[items]` (**list**) [*matching-items*]
: Convert a sequence of C values to a Python list with the same number of items.

`{items}` (**dict**) [*matching-items*]
: Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the **SystemError** exception is set and `NULL` returned.

PyObject *Py_VaBuildValue(const char *format, va_list vargs)
: *Return value: New reference. Part of the Stable ABI.*
Identical to **Py_BuildValue()**, except that it accepts a va_list rather than a variable number of arguments.

String conversion and formatting

Functions for number conversion and formatted string output.

int PyOS_snprintf(char *str, size_t size, const char *format, ...)

> *Part of the Stable ABI.*
> Output not more than *size* bytes to *str* according to the format string *format* and the extra arguments. See the Unix man page *snprintf(3)*.

int PyOS_vsnprintf(char *str, size_t size, const char *format, va_list va)

> *Part of the Stable ABI.*
> Output not more than *size* bytes to *str* according to the format string *format* and the variable argument list *va*. Unix man page *vsnprintf(3)*.

`PyOS_snprintf()` and **`PyOS_vsnprintf()`** wrap the Standard C library functions **`snprintf()`** and **`vsnprintf()`**. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[size-1]` is always `'\0'` upon return. They never write more than *size* bytes (including the trailing `'\0'`) into str. Both functions require that `str != NULL`, `size > 0`, `format != NULL` and `size < INT_MAX`. Note that this means there is no equivalent to the C99 `n = snprintf(NULL, 0, ...)` which would determine the necessary buffer size.

The return value (*rv*) for these functions should be interpreted as follows:

- When `0 <= rv < size`, the output conversion was

successful and *rv* characters were written to *str* (excluding the trailing `'\0'` byte at `str[rv]`).

- When `rv >= size`, the output conversion was truncated and a buffer with `rv + 1` bytes would have been needed to succeed. `str[size-1]` is `'\0'` in this case.
- When `rv < 0`, "something bad happened." `str[size-1]` is `'\0'` in this case too, but the rest of *str* is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

double PyOS_string_to_double(const char *s, char **endptr, PyObject *overflow_exception)

Part of the Stable ABI.
Convert a string `s` to a double, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python's **`float()`** constructor, except that `s` must not have leading or trailing whitespace. The conversion is independent of the current locale.

If `endptr` is `NULL`, convert the whole string. Raise **`ValueError`** and return `-1.0` if the string is not a valid representation of a floating-point number.

If endptr is not `NULL`, convert as much of the string as possible and set `*endptr` to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set `*endptr` to point to the beginning of the string, raise ValueError, and return `-1.0`.

If `s` represents a value that is too large to store in a float (for example, `"1e500"` is such a string on many platforms) then if `overflow_exception` is `NULL` return `Py_HUGE_VAL` (with an appropriate sign) and don't set any exception. Otherwise, `overflow_exception` must point to a Python exception object; raise that exception and return `-1.0`. In both cases, set `*endptr` to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-of-memory error), set the appropriate Python exception and return `-1.0`.

New in version 3.1.

char *PyOS_double_to_string(double val, char format_code, int precision, int flags, int *ptype)

Part of the Stable ABI.
Convert a double *val* to a string using supplied *format_code*, *precision*, and *flags*.

format_code must be one of `'e'`, `'E'`, `'f'`, `'F'`, `'g'`, `'G'` or `'r'`. For `'r'`, the supplied *precision* must be 0 and is ignored. The `'r'` format code specifies the standard **`repr()`** format.

flags can be zero or more of the values `Py_DTSF_SIGN`, `Py_DTSF_ADD_DOT_0`, or `Py_DTSF_ALT`, or-ed together:

- `Py_DTSF_SIGN` means to always precede the returned string with a sign character, even if *val* is non-negative.
- `Py_DTSF_ADD_DOT_0` means to ensure that the returned string will not look like an integer.
- `Py_DTSF_ALT` means to apply "alternate" formatting rules. See the documentation for the **`PyOS_snprintf()`** `'#'` specifier for details.

If *ptype* is non-`NULL`, then the value it points to will be set to one of `Py_DTST_FINITE`, `Py_DTST_INFINITE`, or `Py_DTST_NAN`, signifying that *val* is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to *buffer* with the converted string or `NULL` if the conversion failed. The caller is responsible for freeing the returned string by calling **`PyMem_Free()`**.

New in version 3.1.

int PyOS_stricmp(const char *s1, const char *s2)

Case insensitive comparison of strings. The function works almost identically to **`strcmp()`** except that it ignores the case.

int PyOS_strnicmp(const char *s1, const char *s2, Py_ssize_t size)

Case insensitive comparison of strings. The function works almost identically to **`strncmp()`** except that it ignores the case.

Reflection

PyObject *PyEval_GetBuiltins(void)

Return value: Borrowed reference. Part of the Stable ABI.
Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

PyObject *PyEval_GetLocals(void)

Return value: Borrowed reference. Part of the Stable ABI.
Return a dictionary of the local variables in the current execution frame, or `NULL` if no frame is currently executing.

PyObject *PyEval_GetGlobals(void)

Return value: Borrowed reference. Part of the Stable ABI.
Return a dictionary of the global variables in the current execution frame, or `NULL` if no frame is currently executing.

PyFrameObject *PyEval_GetFrame(void)

Return value: Borrowed reference. Part of the Stable ABI.
Return the current thread state's frame, which is `NULL` if no frame is currently executing.

See also **`PyThreadState_GetFrame()`**.

const char *PyEval_GetFuncName(PyObject *func)

Part of the Stable ABI.
Return the name of *func* if it is a function, class or instance object, else the name of *funcs* type.

const char *PyEval_GetFuncDesc(PyObject *func)

Part of the Stable ABI.
Return a description string, depending on the type of *func*.

Return values include “()” for functions and methods, ” constructor”, ” instance”, and ” object”. Concatenated with the result of **`PyEval_GetFuncName()`**, the result will be a description of *func*.

Codec registry and support functions

int PyCodec_Register(PyObject *search_function)

Part of the Stable ABI.
Register a new codec search function.

As side effect, this tries to load the **encodings** package, if not yet done, to make sure that it is always first in the list of search functions.

int PyCodec_Unregister(PyObject *search_function)

Part of the Stable ABI since version 3.10.
Unregister a codec search function and clear the registry's cache. If the search function is not registered, do nothing. Return 0 on success. Raise an exception and return -1 on error.

New in version 3.10.

int PyCodec_KnownEncoding(const char *encoding)

Part of the Stable ABI.
Return `1` or `0` depending on whether there is a registered codec for the given *encoding*. This function always succeeds.

PyObject *PyCodec_Encode(PyObject *object, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Generic codec based encoding API.

object is passed through the encoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined

for the codec. Raises a **LookupError** if no encoder can be found.

PyObject *PyCodec_Decode(PyObject *object, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Generic codec based decoding API.

object is passed through the decoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a **LookupError** if no encoder can be found.

Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a **KeyError** is set and `NULL` returned.

PyObject *PyCodec_Encoder(const char *encoding)

Return value: New reference. Part of the Stable ABI.
Get an encoder function for the given *encoding*.

PyObject *PyCodec_Decoder(const char *encoding)

Return value: New reference. Part of the Stable ABI.
Get a decoder function for the given *encoding*.

PyObject *PyCodec_IncrementalEncoder(const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get an **IncrementalEncoder** object for the given *encoding*.

PyObject *PyCodec_IncrementalDecoder(const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get an **IncrementalDecoder** object for the given *encoding*.

PyObject *PyCodec_StreamReader(const char *encoding, PyObject *stream, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get a **StreamReader** factory function for the given *encoding*.

PyObject *PyCodec_StreamWriter(const char *encoding, PyObject *stream, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get a **StreamWriter** factory function for the given *encoding*.

Registry API for Unicode encoding error handlers

int PyCodec_RegisterError(const char *name, PyObject *error)

Part of the Stable ABI.
Register the error handling callback function *error* under the given *name*. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and *name* is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of **UnicodeEncodeError**, **UnicodeDecodeError** or **UnicodeTranslateError** that holds information about the problematic sequence of characters or bytes and their offset in the original string (see Unicode Exception Objects for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return `0` on success, `-1` on error.

PyObject *PyCodec_LookupError(const char *name)

Return value: New reference. Part of the Stable ABI.
Lookup the error handling callback function registered under *name*. As a special case `NULL` can be passed, in which case the error handling callback for "strict" will be returned.

PyObject *PyCodec_StrictErrors(PyObject *exc)

Return value: Always NULL. Part of the Stable ABI.
Raise *exc* as an exception.

PyObject *PyCodec_IgnoreErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Ignore the unicode error, skipping the faulty input.

PyObject *PyCodec_ReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Replace the unicode encode error with `?` or `U+FFFD`.

PyObject *PyCodec_XMLCharRefReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Replace the unicode encode error with XML character references.

PyObject *PyCodec_BackslashReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Replace the unicode encode error with backslash escapes (`\x`, `\u` and `\U`).

PyObject *PyCodec_NameReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI since version 3.7.
Replace the unicode encode error with `\N{...}` escapes.

New in version 3.5.

Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by **`PyList_New()`**, but whose items have not been set to some non-`NULL` value yet.

Object Protocol

PyObject *Py_NotImplemented

The `NotImplemented` singleton, used to signal that an operation is not implemented for the given type combination.

Py_RETURN_NOTIMPLEMENTED

Properly handle returning **`Py_NotImplemented`** from within a C function (that is, increment the reference count of NotImplemented and return it).

int PyObject_Print(PyObject *o, FILE *fp, int flags)

Print an object *o*, on file *fp*. Returns `-1` on error. The flags argument is used to enable certain printing options. The only option currently supported is **`Py_PRINT_RAW`**; if given, the **`str()`** of the object is written instead of the **`repr()`**.

int PyObject_HasAttr(PyObject *o, PyObject *attr_name)

Part of the Stable ABI.
Returns `1` if *o* has the attribute *attr_name*, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

Note that exceptions which occur while calling **`__getattr__()`** and **`__getattribute__()`** methods will get suppressed. To get error reporting use **`PyObject_GetAttr()`** instead.

int PyObject_HasAttrString(PyObject *o, const char *attr_name)

Part of the Stable ABI.
Returns `1` if *o* has the attribute *attr_name*, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

Note that exceptions which occur while calling **`__getattr__()`** and **`__getattribute__()`** methods and creating a temporary string object will get suppressed. To get error reporting use **`PyObject_GetAttrString()`** instead.

PyObject *PyObject_GetAttr(PyObject *o, PyObject *attr_name)

Return value: New reference. Part of the Stable ABI.
Retrieve an attribute named *attr_name* from object *o*. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

PyObject *PyObject_GetAttrString(PyObject *o, const char *attr_name)

Return value: New reference. Part of the Stable ABI.
Retrieve an attribute named *attr_name* from object *o*. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

PyObject *PyObject_GenericGetAttr(PyObject *o, PyObject *name)

Return value: New reference. Part of the Stable ABI.
Generic attribute getter function that is meant to be put into a type object's `tp_getattro` slot. It looks for a descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's **`__dict__`** (if present). As outlined in Implementing Descriptors, data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an **`AttributeError`** is raised.

int PyObject_SetAttr(PyObject *o, PyObject *attr_name, PyObject *v)

Part of the Stable ABI.
Set the value of the attribute named *attr_name*, for object *o*, to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If *v* is `NULL`, the attribute is deleted. This behaviour is

deprecated in favour of using **PyObject_DelAttr()**, but there are currently no plans to remove it.

int PyObject_SetAttrString(PyObject *o, const char *attr_name, PyObject *v)

Part of the Stable ABI.
Set the value of the attribute named *attr_name*, for object *o*, to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If *v* is `NULL`, the attribute is deleted, but this feature is deprecated in favour of using **PyObject_DelAttrString()**.

int PyObject_GenericSetAttr(PyObject *o, PyObject *name, PyObject *value)

Part of the Stable ABI.
Generic attribute setter and deleter function that is meant to be put into a type object's **tp_setattro** slot. It looks for a data descriptor in the dictionary of classes in the object's MRO, and if found it takes preference over setting or deleting the attribute in the instance dictionary. Otherwise, the attribute is set or deleted in the object's **__dict__** (if present). On success, `0` is returned, otherwise an **AttributeError** is raised and `-1` is returned.

int PyObject_DelAttr(PyObject *o, PyObject *attr_name)

Delete attribute named *attr_name*, for object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

int PyObject_DelAttrString(PyObject *o, const char *attr_name)

Delete attribute named *attr_name*, for object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

PyObject *PyObject_GenericGetDict(PyObject *o, void *context)

Return value: New reference. Part of the Stable ABI since version 3.10.
A generic implementation for the getter of a `__dict__` descriptor. It creates the dictionary if necessary.

This function may also be called to get the **`__dict__`** of the object *o*. Pass `NULL` for *context* when calling it. Since this function may need to allocate memory for the dictionary, it may be more efficient to call **`PyObject_GetAttr()`** when accessing an attribute on the object.

On failure, returns `NULL` with an exception set.

New in version 3.3.

int PyObject_GenericSetDict(PyObject *o, PyObject *value, void *context)

Part of the Stable ABI since version 3.7.
A generic implementation for the setter of a `__dict__` descriptor. This implementation does not allow the dictionary to be deleted.

New in version 3.3.

PyObject **_PyObject_GetDictPtr(PyObject *obj)

Return a pointer to **`__dict__`** of the object *obj*. If there is no `__dict__`, return `NULL` without setting an exception.

This function may need to allocate memory for the dictionary, so it may be more efficient to call **`PyObject_GetAttr()`** when accessing an attribute on the object.

PyObject *PyObject_RichCompare(PyObject *o1, PyObject *o2, int opid)

Return value: New reference. Part of the Stable ABI.
Compare the values of *o1* and *o2* using the operation

specified by *opid*, which must be one of **Py_LT**, **Py_LE**, **Py_EQ**, **Py_NE**, **Py_GT**, or **Py_GE**, corresponding to <, <=, ==, !=, >, or >= respectively. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to *opid*. Returns the value of the comparison on success, or `NULL` on failure.

int PyObject_RichCompareBool(PyObject *o1, PyObject *o2, int opid)

Part of the Stable ABI.
Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of **Py_LT**, **Py_LE**, **Py_EQ**, **Py_NE**, **Py_GT**, or **Py_GE**, corresponding to <, <=, ==, !=, >, or >= respectively. Returns `-1` on error, `0` if the result is false, `1` otherwise. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to *opid*.

Note

If *o1* and *o2* are the same object, **PyObject_RichCompareBool()** will always return `1` for **Py_EQ** and `0` for **Py_NE**.

PyObject *PyObject_Repr(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Compute a string representation of object *o*. Returns the string representation on success, `NULL` on failure. This is the equivalent of the Python expression `repr(o)`. Called by the **repr()** built-in function.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject *PyObject_ASCII(PyObject *o)

Return value: New reference. Part of the Stable ABI.
As **PyObject_Repr()**, compute a string representation of

object *o*, but escape the non-ASCII characters in the string returned by **PyObject_Repr()** with `\x`, `\u` or `\U` escapes. This generates a string similar to that returned by **PyObject_Repr()** in Python 2. Called by the **ascii()** built-in function.

PyObject *PyObject_Str(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Compute a string representation of object *o*. Returns the string representation on success, `NULL` on failure. This is the equivalent of the Python expression `str(o)`. Called by the **str()** built-in function and, therefore, by the **print()** function.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject *PyObject_Bytes(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Compute a bytes representation of object *o*. `NULL` is returned on failure and a bytes object on success. This is equivalent to the Python expression `bytes(o)`, when *o* is not an integer. Unlike `bytes(o)`, a TypeError is raised when *o* is an integer instead of a zero-initialized bytes object.

int PyObject_IsSubclass(PyObject *derived, PyObject *cls)

Part of the Stable ABI.
Return `1` if the class *derived* is identical to or derived from the class *cls*, otherwise return `0`. In case of an error, return `-1`.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a **__subclasscheck__()** method, it will be

called to determine the subclass status as described in **PEP 3119** [https://peps.python.org/pep-3119/]. Otherwise, *derived* is a subclass of *cls* if it is a direct or indirect subclass, i.e. contained in `cls.__mro__`.

Normally only class objects, i.e. instances of **`type`** or a derived class, are considered classes. However, objects can override this by having a **`__bases__`** attribute (which must be a tuple of base classes).

int PyObject_IsInstance(PyObject *inst, PyObject *cls)

Part of the Stable ABI.
Return `1` if *inst* is an instance of the class *cls* or a subclass of *cls*, or `0` if not. On error, returns `-1` and sets an exception.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a **`__instancecheck__()`** method, it will be called to determine the subclass status as described in **PEP 3119** [https://peps.python.org/pep-3119/]. Otherwise, *inst* is an instance of *cls* if its class is a subclass of *cls*.

An instance *inst* can override what is considered its class by having a **`__class__`** attribute.

An object *cls* can override if it is considered a class, and what its base classes are, by having a **`__bases__`** attribute (which must be a tuple of base classes).

Py_hash_t PyObject_Hash(PyObject *o)

Part of the Stable ABI.
Compute and return the hash value of an object *o*. On failure, return `-1`. This is the equivalent of the Python expression `hash(o)`.

Changed in version 3.2: The return type is now Py_hash_t. This is a signed integer the same size as **`Py_ssize_t`**.

Py_hash_t PyObject_HashNotImplemented(PyObject *o)

Part of the Stable ABI.
Set a **TypeError** indicating that `type(o)` is not hashable and return `-1`. This function receives special treatment when stored in a `tp_hash` slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.

int PyObject_IsTrue(PyObject *o)

Part of the Stable ABI.
Returns `1` if the object *o* is considered to be true, and `0` otherwise. This is equivalent to the Python expression `not not o`. On failure, return `-1`.

int PyObject_Not(PyObject *o)

Part of the Stable ABI.
Returns `0` if the object *o* is considered to be true, and `1` otherwise. This is equivalent to the Python expression `not o`. On failure, return `-1`.

PyObject *PyObject_Type(PyObject *o)

Return value: New reference. Part of the Stable ABI.
When *o* is non-`NULL`, returns a type object corresponding to the object type of object *o*. On failure, raises **SystemError** and returns `NULL`. This is equivalent to the Python expression `type(o)`. This function increments the reference count of the return value. There's really no reason to use this function instead of the **Py_TYPE()** function, which returns a pointer of type PyTypeObject*, except when the incremented reference count is needed.

int PyObject_TypeCheck(PyObject *o, PyTypeObject *type)

Return non-zero if the object *o* is of type *type* or a subtype of *type*, and `0` otherwise. Both parameters must be non-`NULL`.

Py_ssize_t PyObject_Size(PyObject *o)
Py_ssize_t PyObject_Length(PyObject *o)

Part of the Stable ABI.

Return the length of object *o*. If the object *o* provides either the sequence and mapping protocols, the sequence length is returned. On error, `-1` is returned. This is the equivalent to the Python expression `len(o)`.

Py_ssize_t PyObject_LengthHint(PyObject *o, Py_ssize_t defaultvalue)

Return an estimated length for the object *o*. First try to return its actual length, then an estimate using **`__length_hint__()`**, and finally return the default value. On error return `-1`. This is the equivalent to the Python expression `operator.length_hint(o, defaultvalue)`.

New in version 3.4.

PyObject *PyObject_GetItem(PyObject *o, PyObject *key)

Return value: New reference. Part of the Stable ABI.
Return element of *o* corresponding to the object *key* or `NULL` on failure. This is the equivalent of the Python expression `o[key]`.

int PyObject_SetItem(PyObject *o, PyObject *key, PyObject *v)

Part of the Stable ABI.
Map the object *key* to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o[key] = v`. This function *does not* steal a reference to *v*.

int PyObject_DelItem(PyObject *o, PyObject *key)

Part of the Stable ABI.
Remove the mapping for the object *key* from the object *o*. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

PyObject *PyObject_Dir(PyObject *o)

Return value: New reference. Part of the Stable ABI.

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but **`PyErr_Occurred()`** will return false.

PyObject *PyObject_GetIter(PyObject *o)

Return value: New reference. Part of the Stable ABI.
This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises **`TypeError`** and returns `NULL` if the object cannot be iterated.

PyObject *PyObject_GetAIter(PyObject *o)

Return value: New reference. Part of the Stable ABI since version 3.10.
This is the equivalent to the Python expression `aiter(o)`. Takes an **`AsyncIterable`** object and returns an **`AsyncIterator`** for it. This is typically a new iterator but if the argument is an **`AsyncIterator`**, this returns itself. Raises **`TypeError`** and returns `NULL` if the object cannot be iterated.

New in version 3.10.

Call Protocol

CPython supports two different calling protocols: *tp_call* and vectorcall.

The *tp_call* Protocol

Instances of classes that set **`tp_call`** are callable. The signature of the slot is:

```
PyObject *tp_call(PyObject *callable, PyObject *args, Py
```

A call is made using a tuple for the positional arguments and a dict for the keyword arguments, similarly to `callable(*args, **kwargs)` in Python code. *args* must be non-NULL (use an empty tuple if there are no arguments) but *kwargs* may be *NULL* if there are no keyword arguments.

This convention is not only used by *tp_call*: **`tp_new`** and **`tp_init`** also pass arguments this way.

To call an object, use **`PyObject_Call()`** or another call API.

The Vectorcall Protocol

New in version 3.9.

The vectorcall protocol was introduced in **PEP 590** [https://peps.python.org/pep-0590/] as an additional protocol for making calls more efficient.

As rule of thumb, CPython will prefer the vectorcall for internal calls if the callable supports it. However, this is not a hard rule. Additionally, some third-party extensions use *tp_call* directly (rather than using **`PyObject_Call()`**). Therefore, a class supporting vectorcall must also implement **`tp_call`**. Moreover, the callable

must behave the same regardless of which protocol is used. The recommended way to achieve this is by setting **tp_call** to **PyVectorcall_Call()**. This bears repeating:

Warning

A class supporting vectorcall **must** also implement **tp_call** with the same semantics.

A class should not implement vectorcall if that would be slower than *tp_call*. For example, if the callee needs to convert the arguments to an args tuple and kwargs dict anyway, then there is no point in implementing vectorcall.

Classes can implement the vectorcall protocol by enabling the **Py_TPFLAGS_HAVE_VECTORCALL** flag and setting **tp_vectorcall_offset** to the offset inside the object structure where a *vectorcallfunc* appears. This is a pointer to a function with the following signature:

typedef PyObject *(*vectorcallfunc)(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwnames)

- *callable* is the object being called.
- *args* is a C array consisting of the positional arguments followed by the
  values of the keyword arguments. This can be *NULL* if there are no arguments.
- *nargsf* is the number of positional arguments plus possibly the **PY_VECTORCALL_ARGUMENTS_OFFSET** flag. To get the actual number of positional arguments from *nargsf*, use **PyVectorcall_NARGS()**.
- *kwnames* is a tuple containing the names of the keyword arguments;
  in other words, the keys of the kwargs dict. These names must be strings (instances of `str` or a subclass)

and they must be unique. If there are no keyword arguments, then *kwnames* can instead be *NULL*.

PY_VECTORCALL_ARGUMENTS_OFFSET

If this flag is set in a vectorcall *nargsf* argument, the callee is allowed to temporarily change `args[-1]`. In other words, *args* points to argument 1 (not 0) in the allocated vector. The callee must restore the value of `args[-1]` before returning.

For **`PyObject_VectorcallMethod()`**, this flag means instead that `args[0]` may be changed.

Whenever they can do so cheaply (without additional allocation), callers are encouraged to use **`PY_VECTORCALL_ARGUMENTS_OFFSET`**. Doing so will allow callables such as bound methods to make their onward calls (which include a prepended *self* argument) very efficiently.

To call an object that implements vectorcall, use a call API function as with any other callable. **`PyObject_Vectorcall()`** will usually be most efficient.

Note

In CPython 3.8, the vectorcall API and related functions were available provisionally under names with a leading underscore: `_PyObject_Vectorcall`, `_Py_TPFLAGS_HAVE_VECTORCALL`, `_PyObject_VectorcallMethod`, `_PyVectorcall_Function`, `_PyObject_CallOneArg`, `_PyObject_CallMethodNoArgs`, `_PyObject_CallMethodOneArg`. Additionally, `PyObject_VectorcallDict` was available as `_PyObject_FastCallDict`. The old names are still defined as aliases of the new, non-underscored names.

Recursion Control

When using *tp_call*, callees do not need to worry about recursion:

CPython uses **Py_EnterRecursiveCall()** and **Py_LeaveRecursiveCall()** for calls made using *tp_call*.

For efficiency, this is not the case for calls done using vectorcall: the callee should use *Py_EnterRecursiveCall* and *Py_LeaveRecursiveCall* if needed.

Vectorcall Support API

Py_ssize_t PyVectorcall_NARGS(size_t nargsf)

Given a vectorcall *nargsf* argument, return the actual number of arguments. Currently equivalent to:

```
(Py_ssize_t)(nargsf & ~PY_VECTORCALL_ARGUMENTS_OFFS
```

However, the function `PyVectorcall_NARGS` should be used to allow for future extensions.

New in version 3.8.

vectorcallfunc PyVectorcall_Function(PyObject *op)

If *op* does not support the vectorcall protocol (either because the type does not or because the specific instance does not), return *NULL*. Otherwise, return the vectorcall function pointer stored in *op*. This function never raises an exception.

This is mostly useful to check whether or not *op* supports vectorcall, which can be done by checking `PyVectorcall_Function(op) != NULL`.

New in version 3.8.

PyObject *PyVectorcall_Call(PyObject *callable, PyObject *tuple, PyObject *dict)

Call *callable*'s **vectorcallfunc** with positional and keyword arguments given in a tuple and dict, respectively.

This is a specialized function, intended to be put in the **tp_call** slot or be used in an implementation of `tp_call`.

It does not check the **Py_TPFLAGS_HAVE_VECTORCALL** flag and it does not fall back to `tp_call`.

New in version 3.8.

Object Calling API

Various functions are available for calling a Python object. Each converts its arguments to a convention supported by the called object – either *tp_call* or vectorcall. In order to do as little conversion as possible, pick one that best fits the format of data you have available.

The following table summarizes the available functions; please see individual documentation for details.

PyObject_Call()	
PyObject_CallNoArgs()	
PyObject_CallOneArg()	
PyObject_CallObject()	
PyObject_CallFunction()	
PyObject_CallMethod()	
PyObject_CallFunctionObjArgs()	
PyObject_CallMethodObjArgs()	
PyObject_CallMethodNoArgs()	
PyObject_CallMethodOneArg()	
PyObject_Vectorcall()	
PyObject_VectorcallDict()	
PyObject_VectorcallMethod()	

PyObject *PyObject_Call(PyObject *callable, PyObject *args, PyObject *kwargs)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with arguments given by the tuple *args*, and named arguments given by the dictionary *kwargs*.

args must not be *NULL*; use an empty tuple if no arguments

are needed. If no named arguments are needed, *kwargs* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args, **kwargs)`.

PyObject *PyObject_CallNoArgs(PyObject *callable)

Part of the Stable ABI since version 3.10.
Call a callable Python object *callable* without any arguments. It is the most efficient way to call a callable Python object without any argument.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

PyObject *PyObject_CallOneArg(PyObject *callable, PyObject *arg)

Call a callable Python object *callable* with exactly 1 positional argument *arg* and no keyword arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

PyObject *PyObject_CallObject(PyObject *callable, PyObject *args)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with arguments given by the tuple *args*. If no arguments are needed, then *args* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args)`.

PyObject *PyObject_CallFunction(PyObject *callable, const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with a variable number of C arguments. The C arguments are described using a **`Py_BuildValue()`** style format string. The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args)`.

Note that if you only pass PyObject* args, **`PyObject_CallFunctionObjArgs()`** is a faster alternative.

Changed in version 3.4: The type of *format* was changed from `char *`.

PyObject *PyObject_CallMethod(PyObject *obj, const char *name, const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Call the method named *name* of object *obj* with a variable number of C arguments. The C arguments are described by a **`Py_BuildValue()`** format string that should produce a tuple.

The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `obj.name(arg1, arg2, ...)`.

Note that if you only pass PyObject* args, **`PyObject_CallMethodObjArgs()`** is a faster alternative.

Changed in version 3.4: The types of *name* and *format* were changed from `char *`.

PyObject *PyObject_CallFunctionObjArgs(PyObject *callable, ...)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(arg1, arg2, ...)`.

PyObject *PyObject_CallMethodObjArgs(PyObject *obj, PyObject *name, ...)

Return value: New reference. Part of the Stable ABI.
Call a method of the Python object *obj*, where the name of the method is given as a Python string object in *name*. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

PyObject *PyObject_CallMethodNoArgs(PyObject *obj, PyObject *name)

Call a method of the Python object *obj* without arguments, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

PyObject *PyObject_CallMethodOneArg(PyObject *obj, PyObject *name, PyObject *arg)

Call a method of the Python object *obj* with a single positional argument *arg*, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

PyObject *PyObject_Vectorcall(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwnames)

Call a callable Python object *callable*. The arguments are the same as for **`vectorcallfunc`**. If *callable* supports vectorcall, this directly calls the vectorcall function stored in *callable*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

PyObject *PyObject_VectorcallDict(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwdict)

Call *callable* with positional arguments passed exactly as in the vectorcall protocol, but with keyword arguments passed as a dictionary *kwdict*. The *args* array contains only the positional arguments.

Regardless of which protocol is used internally, a conversion of arguments needs to be done. Therefore, this function should only be used if the caller already has a dictionary ready to use for the keyword arguments, but not a tuple for the positional arguments.

New in version 3.9.

PyObject *PyObject_VectorcallMethod(PyObject *name, PyObject *const *args, size_t nargsf, PyObject *kwnames)

Call a method using the vectorcall calling convention. The name of the method is given as a Python string *name*. The object whose method is called is *args[0]*, and the *args* array starting at *args[1]* represents the arguments of the call. There must be at least one positional argument. *nargsf* is the number of positional arguments including *args[0]*, plus **PY_VECTORCALL_ARGUMENTS_OFFSET** if the value of `args[0]` may temporarily be changed. Keyword arguments can be passed just like in **PyObject_Vectorcall()**.

If the object has the **Py_TPFLAGS_METHOD_DESCRIPTOR** feature, this will call the unbound method object with the full *args* vector as arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

New in version 3.9.

Call Support API

int PyCallable_Check(PyObject *o)

Part of the Stable ABI.
Determine if the object *o* is callable. Return `1` if the object is callable and `0` otherwise. This function always succeeds.

Number Protocol

int PyNumber_Check(PyObject *o)

Part of the Stable ABI.
Returns `1` if the object *o* provides numeric protocols, and false otherwise. This function always succeeds.

Changed in version 3.8: Returns `1` if *o* is an index integer.

PyObject *PyNumber_Add(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of adding *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject *PyNumber_Subtract(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. This is the equivalent of the Python expression `o1 - o2`.

PyObject *PyNumber_Multiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 * o2`.

PyObject *PyNumber_MatrixMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI since version 3.7.
Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 @ o2`.

New in version 3.5.

PyObject *PyNumber_FloorDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return the floor of *o1* divided by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 // o2`.

PyObject *PyNumber_TrueDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is "approximate" because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. This is the equivalent of the Python expression `o1 / o2`.

PyObject *PyNumber_Remainder(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 % o2`.

PyObject *PyNumber_Divmod(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
See the built-in function **`divmod()`**. Returns `NULL` on failure. This is the equivalent of the Python expression `divmod(o1, o2)`.

PyObject *PyNumber_Power(PyObject *o1, PyObject *o2, PyObject *o3)

Return value: New reference. Part of the Stable ABI.
See the built-in function **`pow()`**. Returns `NULL` on failure. This is the equivalent of the Python expression `pow(o1, o2, o3)`, where *o3* is optional. If *o3* is to be ignored, pass **`Py_None`** in its place (passing `NULL` for *o3* would cause an illegal memory access).

PyObject *PyNumber_Negative(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the negation of *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `-o`.

PyObject *PyNumber_Positive(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `+o`.

PyObject *PyNumber_Absolute(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the absolute value of *o*, or `NULL` on failure. This is the equivalent of the Python expression `abs(o)`.

PyObject *PyNumber_Invert(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the bitwise negation of *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `~o`.

PyObject *PyNumber_Lshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of left shifting *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 << o2`.

PyObject *PyNumber_Rshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of right shifting *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 >> o2`.

PyObject *PyNumber_And(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the “bitwise and” of *o1* and *o2* on success and `NULL` on failure. This is the equivalent of the Python expression `o1 & o2`.

PyObject *PyNumber_Xor(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the "bitwise exclusive or" of *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 ^ o2`.

PyObject *PyNumber_Or(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the "bitwise or" of *o1* and *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 | o2`.

PyObject *PyNumber_InPlaceAdd(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of adding *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 += o2`.

PyObject *PyNumber_InPlaceSubtract(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 -= o2`.

PyObject *PyNumber_InPlaceMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 *= o2`.

PyObject *PyNumber_InPlaceMatrixMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI since version 3.7.
Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1`

`@= o2`.

New in version 3.5.

PyObject *PyNumber_InPlaceFloorDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the mathematical floor of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 //= o2`.

PyObject *PyNumber_InPlaceTrueDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is "approximate" because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 /= o2`.

PyObject *PyNumber_InPlaceRemainder(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 %= o2`.

PyObject *PyNumber_InPlacePower(PyObject *o1, PyObject *o2, PyObject *o3)

Return value: New reference. Part of the Stable ABI.
See the built-in function **`pow()`**. Returns `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 **= o2` when o3 is **`Py_None`**, or an in-place variant of `pow(o1, o2, o3)`

otherwise. If *o3* is to be ignored, pass **Py_None** in its place (passing `NULL` for *o3* would cause an illegal memory access).

PyObject *PyNumber_InPlaceLshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of left shifting *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 <<= o2`.

PyObject *PyNumber_InPlaceRshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of right shifting *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 >>= o2`.

PyObject *PyNumber_InPlaceAnd(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the "bitwise and" of *o1* and *o2* on success and `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 &= o2`.

PyObject *PyNumber_InPlaceXor(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the "bitwise exclusive or" of *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 ^= o2`.

PyObject *PyNumber_InPlaceOr(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the "bitwise or" of *o1* and *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 |= o2`.

PyObject *PyNumber_Long(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the *o* converted to an integer object on success, or `NULL` on failure. This is the equivalent of the Python expression `int(o)`.

PyObject *PyNumber_Float(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the *o* converted to a float object on success, or `NULL` on failure. This is the equivalent of the Python expression `float(o)`.

PyObject *PyNumber_Index(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the *o* converted to a Python int on success or `NULL` with a **`TypeError`** exception raised on failure.

Changed in version 3.10: The result always has exact type **`int`**. Previously, the result could have been an instance of a subclass of `int`.

PyObject *PyNumber_ToBase(PyObject *n, int base)

Return value: New reference. Part of the Stable ABI.
Returns the integer *n* converted to base *base* as a string. The *base* argument must be one of 2, 8, 10, or 16. For base 2, 8, or 16, the returned string is prefixed with a base marker of `'0b'`, `'0o'`, or `'0x'`, respectively. If *n* is not a Python int, it is converted with **`PyNumber_Index()`** first.

Py_ssize_t PyNumber_AsSsize_t(PyObject *o, PyObject *exc)

Part of the Stable ABI.
Returns *o* converted to a **`Py_ssize_t`** value if *o* can be interpreted as an integer. If the call fails, an exception is raised and `-1` is returned.

If *o* can be converted to a Python int but the attempt to convert to a **`Py_ssize_t`** value would raise an **`OverflowError`**, then the *exc* argument is the type of exception that will be raised (usually **`IndexError`** or

OverflowError). If *exc* is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer.

int PyIndex_Check(PyObject *o)

Part of the Stable ABI since version 3.8.
Returns `1` if *o* is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in), and `0` otherwise. This function always succeeds.

Sequence Protocol

int PySequence_Check(PyObject *o)

Part of the Stable ABI.
Return `1` if the object provides the sequence protocol, and `0` otherwise. Note that it returns `1` for Python classes with a **`__getitem__()`** method, unless they are **`dict`** subclasses, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

Py_ssize_t PySequence_Size(PyObject *o)

Py_ssize_t PySequence_Length(PyObject *o)

Part of the Stable ABI.
Returns the number of objects in sequence *o* on success, and `-1` on failure. This is equivalent to the Python expression `len(o)`.

PyObject *PySequence_Concat(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return the concatenation of *o1* and *o2* on success, and `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject *PySequence_Repeat(PyObject *o, Py_ssize_t count)

Return value: New reference. Part of the Stable ABI.
Return the result of repeating sequence object *o* *count* times, or `NULL` on failure. This is the equivalent of the Python expression `o * count`.

PyObject *PySequence_InPlaceConcat(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return the concatenation of *o1* and *o2* on success, and `NULL` on failure. The operation is done *in-place* when *o1* supports it.

This is the equivalent of the Python expression `o1 += o2`.

PyObject *PySequence_InPlaceRepeat(PyObject *o, Py_ssize_t count)

Return value: New reference. Part of the Stable ABI.
Return the result of repeating sequence object *o* *count* times, or `NULL` on failure. The operation is done *in-place* when *o* supports it. This is the equivalent of the Python expression `o *= count`.

PyObject *PySequence_GetItem(PyObject *o, Py_ssize_t i)

Return value: New reference. Part of the Stable ABI.
Return the *i*th element of *o*, or `NULL` on failure. This is the equivalent of the Python expression `o[i]`.

PyObject *PySequence_GetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

Return value: New reference. Part of the Stable ABI.
Return the slice of sequence object *o* between *i1* and *i2*, or `NULL` on failure. This is the equivalent of the Python expression `o[i1:i2]`.

int PySequence_SetItem(PyObject *o, Py_ssize_t i, PyObject *v)

Part of the Stable ABI.
Assign object *v* to the *i*th element of *o*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o[i] = v`. This function *does not* steal a reference to *v*.

If *v* is `NULL`, the element is deleted, but this feature is deprecated in favour of using **`PySequence_DelItem()`**.

int PySequence_DelItem(PyObject *o, Py_ssize_t i)

Part of the Stable ABI.
Delete the *i*th element of object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i]`.

int PySequence_SetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2, PyObject *v)

Part of the Stable ABI.
Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement `o[i1:i2] = v`.

int PySequence_DelSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

Part of the Stable ABI.
Delete the slice in sequence object *o* from *i1* to *i2*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i1:i2]`.

Py_ssize_t PySequence_Count(PyObject *o, PyObject *value)

Part of the Stable ABI.
Return the number of occurrences of *value* in *o*, that is, return the number of keys for which `o[key] == value`. On failure, return `-1`. This is equivalent to the Python expression `o.count(value)`.

int PySequence_Contains(PyObject *o, PyObject *value)

Part of the Stable ABI.
Determine if *o* contains *value*. If an item in *o* is equal to *value*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `value in o`.

Py_ssize_t PySequence_Index(PyObject *o, PyObject *value)

Part of the Stable ABI.
Return the first index *i* for which `o[i] == value`. On error, return `-1`. This is equivalent to the Python expression `o.index(value)`.

PyObject *PySequence_List(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return a list object with the same contents as the sequence or iterable *o*, or `NULL` on failure. The returned list is guaranteed to be new. This is equivalent to the Python expression

`list(o)`.

PyObject *PySequence_Tuple(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return a tuple object with the same contents as the sequence or iterable *o*, or `NULL` on failure. If *o* is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression `tuple(o)`.

PyObject *PySequence_Fast(PyObject *o, const char *m)

Return value: New reference. Part of the Stable ABI.
Return the sequence or iterable *o* as an object usable by the other `PySequence_Fast*` family of functions. If the object is not a sequence or iterable, raises **`TypeError`** with *m* as the message text. Returns `NULL` on failure.

The `PySequence_Fast*` functions are thus named because they assume *o* is a **`PyTupleObject`** or a **`PyListObject`** and access the data fields of *o* directly.

As a CPython implementation detail, if *o* is already a sequence or list, it will be returned.

Py_ssize_t PySequence_Fast_GET_SIZE(PyObject *o)

Returns the length of *o*, assuming that *o* was returned by **`PySequence_Fast()`** and that *o* is not `NULL`. The size can also be retrieved by calling **`PySequence_Size()`** on *o*, but **`PySequence_Fast_GET_SIZE()`** is faster because it can assume *o* is a list or tuple.

PyObject *PySequence_Fast_GET_ITEM(PyObject *o, Py_ssize_t i)

Return value: Borrowed reference.
Return the *i*th element of *o*, assuming that *o* was returned by **`PySequence_Fast()`**, *o* is not `NULL`, and that *i* is within bounds.

PyObject **PySequence_Fast_ITEMS(PyObject *o)

Return the underlying array of PyObject pointers. Assumes that *o* was returned by **PySequence_Fast()** and *o* is not NULL.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.

PyObject *PySequence_ITEM(PyObject *o, Py_ssize_t i)

Return value: New reference.
Return the *i*th element of *o* or NULL on failure. Faster form of **PySequence_GetItem()** but without checking that **PySequence_Check()** on *o* is true and without adjustment for negative indices.

Mapping Protocol

See also **`PyObject_GetItem()`**, **`PyObject_SetItem()`** and **`PyObject_DelItem()`**.

int PyMapping_Check(PyObject *o)

Part of the Stable ABI.
Return `1` if the object provides the mapping protocol or supports slicing, and `0` otherwise. Note that it returns `1` for Python classes with a **`__getitem__()`** method, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

Py_ssize_t PyMapping_Size(PyObject *o)
Py_ssize_t PyMapping_Length(PyObject *o)

Part of the Stable ABI.
Returns the number of keys in object *o* on success, and `-1` on failure. This is equivalent to the Python expression `len(o)`.

PyObject *PyMapping_GetItemString(PyObject *o, const char *key)

Return value: New reference. Part of the Stable ABI.
Return element of *o* corresponding to the string *key* or `NULL` on failure. This is the equivalent of the Python expression `o[key]`. See also **`PyObject_GetItem()`**.

int PyMapping_SetItemString(PyObject *o, const char *key, PyObject *v)

Part of the Stable ABI.
Map the string *key* to the value *v* in object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `o[key] = v`. See also **`PyObject_SetItem()`**. This function *does not* steal a reference to *v*.

int PyMapping_DelItem(PyObject *o, PyObject *key)

Remove the mapping for the object *key* from the object *o*. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`. This is an alias of **`PyObject_DelItem()`**.

int PyMapping_DelItemString(PyObject *o, const char *key)

Remove the mapping for the string *key* from the object *o*. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

int PyMapping_HasKey(PyObject *o, PyObject *key)

Part of the Stable ABI.
Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

Note that exceptions which occur while calling the **`__getitem__()`** method will get suppressed. To get error reporting use **`PyObject_GetItem()`** instead.

int PyMapping_HasKeyString(PyObject *o, const char *key)

Part of the Stable ABI.
Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

Note that exceptions which occur while calling the **`__getitem__()`** method and creating a temporary string object will get suppressed. To get error reporting use **`PyMapping_GetItemString()`** instead.

PyObject *PyMapping_Keys(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the keys in object *o*. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list

or a tuple.

PyObject *PyMapping_Values(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the values in object *o*. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list or a tuple.

PyObject *PyMapping_Items(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the items in object *o*, where each item is a tuple containing a key-value pair. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list or a tuple.

Iterator Protocol

There are two functions specifically for working with iterators.

int PyIter_Check(PyObject *o)

Part of the Stable ABI since version 3.8.
Return non-zero if the object *o* can be safely passed to **`PyIter_Next()`**, and `0` otherwise. This function always succeeds.

int PyAIter_Check(PyObject *o)

Part of the Stable ABI since version 3.10.
Return non-zero if the object *o* provides the **`AsyncIterator`** protocol, and `0` otherwise. This function always succeeds.

New in version 3.10.

PyObject *PyIter_Next(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return the next value from the iterator *o*. The object must be an iterator according to **`PyIter_Check()`** (it is up to the caller to check this). If there are no remaining values, returns `NULL` with no exception set. If an error occurs while retrieving the item, returns `NULL` and passes along the exception.

To write a loop which iterates over an iterator, the C code should look something like this:

```
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
```

```
    /* propagate error */
}

while ((item = PyIter_Next(iterator))) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_DECREF(item);
}

Py_DECREF(iterator);

if (PyErr_Occurred()) {
    /* propagate error */
}
else {
    /* continue doing useful work */
}
```

type PySendResult

The enum value used to represent different results of **`PyIter_Send()`**.

New in version 3.10.

PySendResult PyIter_Send(PyObject *iter, PyObject *arg, PyObject **presult)

Part of the Stable ABI since version 3.10.
Sends the *arg* value into the iterator *iter*. Returns:

- `PYGEN_RETURN` if iterator returns. Return value is returned via *presult*.
- `PYGEN_NEXT` if iterator yields. Yielded value is returned via *presult*.
- `PYGEN_ERROR` if iterator has raised and exception. *presult* is set to `NULL`.

New in version 3.10.

Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or *buffer*. Such objects include the built-in **`bytes`** and **`bytearray`**, and some extension types like **`array.array`**. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C level in the form of the buffer protocol. This protocol has two sides:

- on the producer side, a type can export a "buffer interface" which allows objects of that type to expose information about their underlying buffer. This interface is described in the section Buffer Object Structures;
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter).

Simple objects such as **`bytes`** and **`bytearray`** expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by an **`array.array`** can be multi-byte values.

An example consumer of the buffer interface is the **`write()`** method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While **`write()`** only needs read-only access to the internal contents of the object passed to it, other methods such as **`readinto()`** need write access to the contents of their argument. The buffer interface allows objects to selectively allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call **PyObject_GetBuffer()** with the right parameters;
- call **PyArg_ParseTuple()** (or one of its siblings) with one of the `y*`, `w*` or `s*` format codes.

In both cases, **PyBuffer_Release()** must be called when the buffer isn't needed anymore. Failure to do so could lead to various issues such as resource leaks.

Buffer structure

Buffer structures (or simply "buffers") are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not **PyObject** pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a memoryview object can be created.

For short instructions how to write an exporting object, see Buffer Object Structures. For obtaining a buffer, see **PyObject_GetBuffer()**.

type Py_buffer

Part of the Stable ABI (including all members) since version 3.11.

void *buf

A pointer to the start of the logical structure described by the buffer fields. This can be any location within the underlying physical memory block of the exporter. For

example, with negative **`strides`** the value may point to the end of the memory block.

For contiguous arrays, the value points to the beginning of the memory block.

PyObject *obj

A new reference to the exporting object. The reference is owned by the consumer and automatically decremented and set to `NULL` by **`PyBuffer_Release()`**. The field is the equivalent of the return value of any standard C-API function.

As a special case, for *temporary* buffers that are wrapped by **`PyMemoryView_FromBuffer()`** or **`PyBuffer_FillInfo()`** this field is `NULL`. In general, exporting objects MUST NOT use this scheme.

Py_ssize_t len

`product(shape) * itemsize`. For contiguous arrays, this is the length of the underlying memory block. For non-contiguous arrays, it is the length that the logical structure would have if it were copied to a contiguous representation.

Accessing `((char *)buf)[0] up to ((char *)buf)[len-1]` is only valid if the buffer has been obtained by a request that guarantees contiguity. In most cases such a request will be **`PyBUF_SIMPLE`** or **`PyBUF_WRITABLE`**.

int readonly

An indicator of whether the buffer is read-only. This field is controlled by the **`PyBUF_WRITABLE`** flag.

Py_ssize_t itemsize

Item size in bytes of a single element. Same as the value of **`struct.calcsize()`** called on non-`NULL` **`format`** values.

Important exception: If a consumer requests a buffer without the **PyBUF_FORMAT** flag, **format** will be set to `NULL`, but **itemsize** still has the value for the original format.

If **shape** is present, the equality `product(shape) * itemsize == len` still holds and the consumer can use **itemsize** to navigate the buffer.

If **shape** is `NULL` as a result of a **PyBUF_SIMPLE** or a **PyBUF_WRITABLE** request, the consumer must disregard **itemsize** and assume `itemsize == 1`.

const char *format

A *NUL* terminated string in **struct** module style syntax describing the contents of a single item. If this is `NULL`, `"B"` (unsigned bytes) is assumed.

This field is controlled by the **PyBUF_FORMAT** flag.

int ndim

The number of dimensions the memory represents as an n-dimensional array. If it is `0`, **buf** points to a single item representing a scalar. In this case, **shape**, **strides** and **suboffsets** MUST be `NULL`.

The macro **PyBUF_MAX_NDIM** limits the maximum number of dimensions to 64. Exporters MUST respect this limit, consumers of multi-dimensional buffers SHOULD be able to handle up to **PyBUF_MAX_NDIM** dimensions.

Py_ssize_t *shape

An array of **Py_ssize_t** of length **ndim** indicating the shape of the memory as an n-dimensional array. Note that `shape[0] * ... * shape[ndim-1] * itemsize` MUST be equal to **len**.

Shape values are restricted to `shape[n] >= 0`. The case `shape[n] == 0` requires special attention. See

complex arrays for further information.

The shape array is read-only for the consumer.

Py_ssize_t *strides

An array of **`Py_ssize_t`** of length **`ndim`** giving the number of bytes to skip to get to a new element in each dimension.

Stride values can be any integer. For regular arrays, strides are usually positive, but a consumer MUST be able to handle the case `strides[n] <= 0`. See complex arrays for further information.

The strides array is read-only for the consumer.

Py_ssize_t *suboffsets

An array of **`Py_ssize_t`** of length **`ndim`**. If `suboffsets[n] >= 0`, the values stored along the nth dimension are pointers and the suboffset value dictates how many bytes to add to each pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

If all suboffsets are negative (i.e. no de-referencing is needed), then this field must be `NULL` (the default value).

This type of array representation is used by the Python Imaging Library (PIL). See complex arrays for further information how to access elements of such an array.

The suboffsets array is read-only for the consumer.

void *internal

This is for use internally by the exporting object. For example, this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed

when the buffer is released. The consumer MUST NOT alter this value.

Buffer request types

Buffers are usually obtained by sending a buffer request to an exporting object via **`PyObject_GetBuffer()`**. Since the complexity of the logical structure of the memory can vary drastically, the consumer uses the *flags* argument to specify the exact buffer type it can handle.

All **`Py_buffer`** fields are unambiguously defined by the request type.

request-independent fields

The following fields are not influenced by *flags* and must always be filled in with the correct values: **`obj`**, **`buf`**, **`len`**, **`itemsize`**, **`ndim`**.

readonly, format

PyBUF_WRITABLE

Controls the **`readonly`** field. If set, the exporter MUST provide a writable buffer or else report failure. Otherwise, the exporter MAY provide either a read-only or writable buffer, but the choice MUST be consistent for all consumers.

PyBUF_FORMAT

Controls the **`format`** field. If set, this field MUST be filled in correctly. Otherwise, this field MUST be `NULL`.

`PyBUF_WRITABLE` can be |'d to any of the flags in the next section. Since **`PyBUF_SIMPLE`** is defined as 0, **`PyBUF_WRITABLE`** can be used as a stand-alone flag to request a simple writable buffer.

PyBUF_FORMAT can be |'d to any of the flags except **PyBUF_SIMPLE**. The latter already implies format `B` (unsigned bytes).

shape, strides, suboffsets

The flags that control the logical structure of the memory are listed in decreasing order of complexity. Note that each flag contains all bits of the flags below it.

Shape	Strides	Suboffsets	
yes	yes	if needed	PyBUF_INDIRECT
yes	yes	NULL	PyBUF_STRIDES
yes	NULL	NULL	PyBUF_ND
NULL	NULL	NULL	PyBUF_SIMPLE

contiguity requests

C or Fortran contiguity can be explicitly requested, with and without stride information. Without stride information, the buffer must be C-contiguous.

Shape	Strides	Suboffsets	
yes	yes	NULL	PyBUF_C_CONTIGUOUS
yes	yes	NULL	PyBUF_F_CONTIGUOUS
yes	yes	NULL	PyBUF_ANY_CONTIGUOUS
yes	NULL	NULL	**PyBUF_ND**

compound requests

All possible requests are fully defined by some combination of the flags in the previous section. For convenience, the buffer protocol provides frequently used combinations as single flags.

In the following table *U* stands for undefined contiguity. The consumer would have to call **PyBuffer_IsContiguous()** to determine contiguity.

Shape	Strides	Suboffsets	
yes	yes	if needed	PyBUF_FULL

[illegible]	[illegible]ULL_RO
[illegible]	[illegible]_RECORDS
[illegible]	[illegible]_RECORDS_RO
[illegible]	[illegible]_STRIDED
[illegible]	[illegible]_STRIDED_RO
[illegible]	[illegible]_CONTIG
[illegible]	[illegible]_CONTIG_RO

Complex arrays

NumPy-style: shape and strides

The logical structure of NumPy-style arrays is defined by **`itemsize`**, **`ndim`**, **`shape`** and **`strides`**.

If `ndim == 0`, the memory location pointed to by **`buf`** is interpreted as a scalar of size **`itemsize`**. In that case, both **`shape`** and **`strides`** are `NULL`.

If **`strides`** is `NULL`, the array is interpreted as a standard n-dimensional C-array. Otherwise, the consumer must access an n-dimensional array as follows:

```
ptr = (char *)buf + indices[0] * strides[0] + ... + indi
item = *((typeof(item) *)ptr);
```

As noted above, **`buf`** can point to any location within the actual memory block. An exporter can check the validity of a buffer with this function:

```
def verify_structure(memlen, itemsize, ndim, shape, stri
    """Verify that the parameters represent a valid arra
       the bounds of the allocated memory:
           char *mem: start of the physical memory block
           memlen: length of the physical memory block
           offset: (char *)buf - mem
    """
    if offset % itemsize:
        return False
    if offset < 0 or offset+itemsize > memlen:
```

```
        return False
    if any(v % itemsize for v in strides):
        return False

    if ndim <= 0:
        return ndim == 0 and not shape and not strides
    if 0 in shape:
        return True

    imin = sum(strides[j]*(shape[j]-1) for j in range(nd
               if strides[j] <= 0)
    imax = sum(strides[j]*(shape[j]-1) for j in range(nd
               if strides[j] > 0)

    return 0 <= offset+imin and offset+imax+itemsize <=
```

PIL-style: shape, strides and suboffsets

In addition to the regular items, PIL-style arrays can contain pointers that must be followed in order to get to the next element in a dimension. For example, the regular three-dimensional C-array `char v[2][2][3]` can also be viewed as an array of 2 pointers to 2 two-dimensional arrays: `char (*v[2])[2][3]`. In suboffsets representation, those two pointers can be embedded at the start of **`buf`**, pointing to two `char x[2][3]` arrays that can be located anywhere in memory.

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-`NULL` strides and suboffsets:

```
void *get_item_pointer(int ndim, void *buf, Py_ssize_t *
                       Py_ssize_t *suboffsets, Py_ssize_
    char *pointer = (char*)buf;
    int i;
    for (i = 0; i < ndim; i++) {
        pointer += strides[i] * indices[i];
        if (suboffsets[i] >=0 ) {
            pointer = *((char**)pointer) + suboffsets[i]
```

```
        }
    }
    return (void*)pointer;
}
```

Buffer-related functions

int PyObject_CheckBuffer(PyObject *obj)

Part of the Stable ABI since version 3.11.
Return `1` if *obj* supports the buffer interface otherwise `0`. When `1` is returned, it doesn't guarantee that **`PyObject_GetBuffer()`** will succeed. This function always succeeds.

int PyObject_GetBuffer(PyObject *exporter, Py_buffer *view, int flags)

Part of the Stable ABI since version 3.11.
Send a request to *exporter* to fill in *view* as specified by *flags*. If the exporter cannot provide a buffer of the exact type, it MUST raise **`PyExc_BufferError`**, set `view->obj` to `NULL` and return `-1`.

On success, fill in *view*, set `view->obj` to a new reference to *exporter* and return 0. In the case of chained buffer providers that redirect requests to a single object, `view->obj` MAY refer to this object instead of *exporter* (See Buffer Object Structures).

Successful calls to **`PyObject_GetBuffer()`** must be paired with calls to **`PyBuffer_Release()`**, similar to **`malloc()`** and **`free()`**. Thus, after the consumer is done with the buffer, **`PyBuffer_Release()`** must be called exactly once.

void PyBuffer_Release(Py_buffer *view)

Part of the Stable ABI since version 3.11.
Release the buffer *view* and decrement the reference count for `view->obj`. This function MUST be called when the buffer is no longer being used, otherwise reference leaks may occur.

It is an error to call this function on a buffer that was not obtained via **PyObject_GetBuffer()**.

Py_ssize_t PyBuffer_SizeFromFormat(const char *format)

Part of the Stable ABI since version 3.11.
Return the implied **itemsize** from **format**. On error, raise an exception and return -1.

New in version 3.9.

int PyBuffer_IsContiguous(const Py_buffer *view, char order)

Part of the Stable ABI since version 3.11.
Return `1` if the memory defined by the *view* is C-style (*order* is `'C'`) or Fortran-style (*order* is `'F'`) contiguous or either one (*order* is `'A'`). Return `0` otherwise. This function always succeeds.

void *PyBuffer_GetPointer(const Py_buffer *view, const Py_ssize_t *indices)

Part of the Stable ABI since version 3.11.
Get the memory area pointed to by the *indices* inside the given *view*. *indices* must point to an array of `view->ndim` indices.

int PyBuffer_FromContiguous(const Py_buffer *view, const void *buf, Py_ssize_t len, char fort)

Part of the Stable ABI since version 3.11.
Copy contiguous *len* bytes from *buf* to *view*. *fort* can be `'C'` or `'F'` (for C-style or Fortran-style ordering). `0` is returned on success, `-1` on error.

int PyBuffer_ToContiguous(void *buf, const Py_buffer *src, Py_ssize_t len, char order)

Part of the Stable ABI since version 3.11.
Copy *len* bytes from *src* to its contiguous representation in *buf*. *order* can be `'C'` or `'F'` or `'A'` (for C-style or Fortran-style ordering or either one). `0` is returned on success, `-1` on

error.

This function fails if *len* != *src->len*.

int PyObject_CopyData(Py_buffer *dest, Py_buffer *src)

Part of the Stable ABI since version 3.11.
Copy data from *src* to *dest* buffer. Can convert between C-style and or Fortran-style buffers.

`0` is returned on success, `-1` on error.

void PyBuffer_FillContiguousStrides(int ndims, Py_ssize_t *shape, Py_ssize_t *strides, int itemsize, char order)

Part of the Stable ABI since version 3.11.
Fill the *strides* array with byte-strides of a contiguous (C-style if *order* is `'C'` or Fortran-style if *order* is `'F'`) array of the given shape with the given number of bytes per element.

int PyBuffer_FillInfo(Py_buffer *view, PyObject *exporter, void *buf, Py_ssize_t len, int readonly, int flags)

Part of the Stable ABI since version 3.11.
Handle buffer requests for an exporter that wants to expose *buf* of size *len* with writability set according to *readonly*. *buf* is interpreted as a sequence of unsigned bytes.

The *flags* argument indicates the request type. This function always fills in *view* as specified by flags, unless *buf* has been designated as read-only and **`PyBUF_WRITABLE`** is set in *flags*.

On success, set `view->obj` to a new reference to *exporter* and return 0. Otherwise, raise **`PyExc_BufferError`**, set `view->obj` to `NULL` and return `-1`;

If this function is used as part of a getbufferproc, *exporter* MUST be set to the exporting object and *flags* must be passed unmodified. Otherwise, *exporter* MUST be `NULL`.

Old Buffer Protocol

Deprecated since version 3.0.

These functions were part of the "old buffer protocol" API in Python 2. In Python 3, this protocol doesn't exist anymore but the functions are still exposed to ease porting 2.x code. They act as a compatibility wrapper around the new buffer protocol, but they don't give you control over the lifetime of the resources acquired when a buffer is exported.

Therefore, it is recommended that you call **`PyObject_GetBuffer()`** (or the `y*` or `w*` format codes with the **`PyArg_ParseTuple()`** family of functions) to get a buffer view over an object, and **`PyBuffer_Release()`** when the buffer view can be released.

int PyObject_AsCharBuffer(PyObject *obj, const char **buffer, Py_ssize_t *buffer_len)

Part of the Stable ABI.
Returns a pointer to a read-only memory location usable as character-based input. The *obj* argument must support the single-segment character buffer interface. On success, returns `0`, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns `-1` and sets a **`TypeError`** on error.

int PyObject_AsReadBuffer(PyObject *obj, const void **buffer, Py_ssize_t *buffer_len)

Part of the Stable ABI.
Returns a pointer to a read-only memory location containing arbitrary data. The *obj* argument must support the single-segment readable buffer interface. On success, returns `0`, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns `-1` and sets a **`TypeError`** on error.

int PyObject_CheckReadBuffer(PyObject *o)

Part of the Stable ABI.
Returns `1` if *o* supports the single-segment readable buffer interface. Otherwise returns `0`. This function always succeeds.

Note that this function tries to get and release a buffer, and exceptions which occur while calling corresponding functions will get suppressed. To get error reporting use **`PyObject_GetBuffer()`** instead.

int PyObject_AsWriteBuffer(PyObject *obj, void **buffer, Py_ssize_t *buffer_len)

Part of the Stable ABI.
Returns a pointer to a writable memory location. The *obj* argument must support the single-segment, character buffer interface. On success, returns `0`, sets *buffer* to the memory location and *buffer_len* to the buffer length. Returns `-1` and sets a **`TypeError`** on error.

Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use **`PyDict_Check()`**. The chapter is structured like the “family tree” of Python object types.

Warning

While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for `NULL` being passed instead of a valid object. Allowing `NULL` to be passed in can cause memory access violations and immediate termination of the interpreter.

Fundamental Objects

This section describes Python type objects and the singleton object `None`.

- Type Objects
  - Creating Heap-Allocated Types
- The **`None`** Object

Numeric Objects

- Integer Objects
- Boolean Objects
- Floating Point Objects

    - Pack and Unpack functions

- Pack functions
- Unpack functions
- Complex Number Objects

    - Complex Numbers as C Structures
    - Complex Numbers as Python Objects

Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

- Bytes Objects
- Byte Array Objects

    - Type check macros
    - Direct API functions
    - Macros

- Unicode Objects and Codecs

    - Unicode Objects

        - Unicode Type
        - Unicode Character Properties
        - Creating and accessing Unicode strings
        - Deprecated Py_UNICODE APIs
        - Locale Encoding
        - File System Encoding
        - wchar_t Support

    - Built-in Codecs

        - Generic Codecs
        - UTF-8 Codecs
        - UTF-32 Codecs
        - UTF-16 Codecs
        - UTF-7 Codecs

        - Unicode-Escape Codecs
        - Raw-Unicode-Escape Codecs
        - Latin-1 Codecs
        - ASCII Codecs
        - Character Map Codecs
        - MBCS codecs for Windows
        - Methods & Slots
    - Methods and Slot Functions

- Tuple Objects
- Struct Sequence Objects
- List Objects

Container Objects

- Dictionary Objects
- Set Objects

Function Objects

- Function Objects
- Instance Method Objects
- Method Objects
- Cell Objects
- Code Objects

Other Objects

- File Objects
- Module Objects
    - Initializing C modules
        - Single-phase initialization
        - Multi-phase initialization
        - Low-level module creation functions
        - Support functions

    - Module lookup

- Iterator Objects
- Descriptor Objects
- Slice Objects
- Ellipsis Object
- MemoryView objects
- Weak Reference Objects
- Capsules
- Frame Objects
- Generator Objects
- Coroutine Objects
- Context Variables Objects
- DateTime Objects
- Objects for Type Hinting

Type Objects

type PyTypeObject

Part of the Limited API (as an opaque struct).
The C structure of the objects used to describe built-in types.

PyTypeObject PyType_Type

Part of the Stable ABI.
This is the type object for type objects; it is the same object as **`type`** in the Python layer.

int PyType_Check(PyObject *o)

Return non-zero if the object *o* is a type object, including instances of types derived from the standard type object. Return 0 in all other cases. This function always succeeds.

int PyType_CheckExact(PyObject *o)

Return non-zero if the object *o* is a type object, but not a subtype of the standard type object. Return 0 in all other cases. This function always succeeds.

unsigned int PyType_ClearCache()

Part of the Stable ABI.
Clear the internal lookup cache. Return the current version tag.

unsigned long PyType_GetFlags(PyTypeObject *type)

Part of the Stable ABI.
Return the **`tp_flags`** member of *type*. This function is primarily meant for use with `Py_LIMITED_API`; the individual flag bits are guaranteed to be stable across Python releases, but access to **`tp_flags`** itself is not part of the limited API.

New in version 3.2.

Changed in version 3.4: The return type is now `unsigned long` rather than `long`.

void PyType_Modified(PyTypeObject *type)

Part of the Stable ABI.
Invalidate the internal lookup cache for the type and all of its subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

int PyType_HasFeature(PyTypeObject *o, int feature)

Return non-zero if the type object *o* sets the feature *feature*. Type features are denoted by single bit flags.

int PyType_IS_GC(PyTypeObject *o)

Return true if the type object includes support for the cycle detector; this tests the type flag **`Py_TPFLAGS_HAVE_GC`**.

int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)

Part of the Stable ABI.
Return true if *a* is a subtype of *b*.

This function only checks for actual subtypes, which means that **`__subclasscheck__()`** is not called on *b*. Call **`PyObject_IsSubclass()`** to do the same check that **`issubclass()`** would do.

PyObject *PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)

Return value: New reference. Part of the Stable ABI.
Generic handler for the **`tp_alloc`** slot of a type object. Use Python's default memory allocation mechanism to allocate a new instance and initialize all its contents to `NULL`.

PyObject *PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwds)

Return value: New reference. Part of the Stable ABI.
Generic handler for the **tp_new** slot of a type object. Create a new instance using the type's **tp_alloc** slot.

int PyType_Ready(PyTypeObject *type)

Part of the Stable ABI.
Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return `0` on success, or return `-1` and sets an exception on error.

Note

If some of the base classes implements the GC protocol and the provided type does not include the **Py_TPFLAGS_HAVE_GC** in its flags, then the GC protocol will be automatically implemented from its parents. On the contrary, if the type being created does include **Py_TPFLAGS_HAVE_GC** in its flags then it **must** implement the GC protocol itself by at least implementing the **tp_traverse** handle.

PyObject *PyType_GetName(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI since version 3.11.
Return the type's name. Equivalent to getting the type's `__name__` attribute.

New in version 3.11.

PyObject *PyType_GetQualName(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI since version 3.11.
Return the type's qualified name. Equivalent to getting the type's `__qualname__` attribute.

New in version 3.11.

void *PyType_GetSlot(PyTypeObject *type, int slot)

Part of the Stable ABI since version 3.4.
Return the function pointer stored in the given slot. If the result is `NULL`, this indicates that either the slot is `NULL`, or that the function was called with invalid parameters. Callers will typically cast the result pointer into the appropriate function type.

See **`PyType_Slot.slot`** for possible values of the *slot* argument.

New in version 3.4.

Changed in version 3.10: **`PyType_GetSlot()`** can now accept all types. Previously, it was limited to heap types.

PyObject *PyType_GetModule(PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Return the module object associated with the given type when the type was created using **`PyType_FromModuleAndSpec()`**.

If no module is associated with the given type, sets **`TypeError`** and returns `NULL`.

This function is usually used to get the module in which a method is defined. Note that in such a method, `PyType_GetModule(Py_TYPE(self))` may not return the intended result. `Py_TYPE(self)` may be a *subclass* of the intended class, and subclasses are not necessarily defined in the same module as their superclass. See **`PyCMethod`** to get the class that defines the method. See **`PyType_GetModuleByDef()`** for cases when `PyCMethod` cannot be used.

New in version 3.9.

void *PyType_GetModuleState(PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Return the state of the module object associated with the given type. This is a shortcut for calling **PyModule_GetState()** on the result of **PyType_GetModule()**.

If no module is associated with the given type, sets **TypeError** and returns `NULL`.

If the *type* has an associated module but its state is `NULL`, returns `NULL` without setting an exception.

New in version 3.9.

PyObject *PyType_GetModuleByDef(PyTypeObject *type, struct PyModuleDef *def)

Find the first superclass whose module was created from the given **PyModuleDef** *def*, and return that module.

If no module is found, raises a **TypeError** and returns `NULL`.

This function is intended to be used together with **PyModule_GetState()** to get module state from slot methods (such as **tp_init** or **nb_add**) and other places where a method's defining class cannot be passed using the **PyCMethod** calling convention.

New in version 3.11.

Creating Heap-Allocated Types

The following functions and structs are used to create heap types.

PyObject *PyType_FromModuleAndSpec(PyObject *module, PyType_Spec *spec, PyObject *bases)

Return value: New reference. Part of the Stable ABI since version 3.10.

Creates and returns a heap type from the *spec* (**Py_TPFLAGS_HEAPTYPE**).

The *bases* argument can be used to specify base classes; it can either be only one class or a tuple of classes. If *bases* is NULL, the *Py_tp_bases* slot is used instead. If that also is NULL, the *Py_tp_base* slot is used instead. If that also is NULL, the new type derives from **object**.

The *module* argument can be used to record the module in which the new class is defined. It must be a module object or NULL. If not NULL, the module is associated with the new type and can later be retrieved with **PyType_GetModule()**. The associated module is not inherited by subclasses; it must be specified for each class individually.

This function calls **PyType_Ready()** on the new type.

New in version 3.9.

Changed in version 3.10: The function now accepts a single class as the *bases* argument and NULL as the tp_doc slot.

PyObject *PyType_FromSpecWithBases(PyType_Spec *spec, PyObject *bases)

Return value: New reference. Part of the Stable ABI since version 3.3.
Equivalent to PyType_FromModuleAndSpec(NULL, spec, bases).

New in version 3.3.

PyObject *PyType_FromSpec(PyType_Spec *spec)

Return value: New reference. Part of the Stable ABI.
Equivalent to PyType_FromSpecWithBases(spec, NULL).

type PyType_Spec

Part of the Stable ABI (including all members).

Structure defining a type's behavior.

const char *PyType_Spec.name
: Name of the type, used to set **PyTypeObject.tp_name**.

int PyType_Spec.basicsize

int PyType_Spec.itemsize
: Size of the instance in bytes, used to set **PyTypeObject.tp_basicsize** and **PyTypeObject.tp_itemsize**.

int PyType_Spec.flags
: Type flags, used to set **PyTypeObject.tp_flags**.

  If the `Py_TPFLAGS_HEAPTYPE` flag is not set, **PyType_FromSpecWithBases()** sets it automatically.

PyType_Slot *PyType_Spec.slots
: Array of **PyType_Slot** structures. Terminated by the special slot value `{0, NULL}`.

type PyType_Slot
: *Part of the Stable ABI (including all members).*
  Structure defining optional functionality of a type, containing a slot ID and a value pointer.

  int PyType_Slot.slot

  A slot ID.

  Slot IDs are named like the field names of the structures **PyTypeObject**, **PyNumberMethods**, **PySequenceMethods**, **PyMappingMethods** and **PyAsyncMethods** with an added `Py_`

prefix. For example, use:

- `Py_tp_dealloc` to set **`PyTypeObject.tp_dealloc`**
- `Py_nb_add` to set **`PyNumberMethods.nb_add`**
- `Py_sq_length` to set **`PySequenceMethods.sq_length`**

The following fields cannot be set at all using **`PyType_Spec`** and **`PyType_Slot`**:

- **`tp_dict`**
- **`tp_mro`**
- **`tp_cache`**
- **`tp_subclasses`**
- **`tp_weaklist`**
- **`tp_vectorcall`**
- **`tp_weaklistoffset`** (see PyMemberDef)
- **`tp_dictoffset`** (see PyMemberDef)
- **`tp_vectorcall_offset`** (see PyMemberDef)

Setting **`Py_tp_bases`** or **`Py_tp_base`** may be problematic on some platforms. To avoid issues, use the *bases* argument of **`PyType_FromSpecWithBases()`** instead.

Changed in version 3.9: Slots in **`PyBufferProcs`** may be set in the unlimited API.

Changed in version 3.11: **`bf_getbuffer`** and **`bf_releasebuffer`** are now available under the limited API.

void *PyType_Slot.pfunc

The desired value of the slot. In most cases, this is a pointer to a function.

Slots other than `Py_tp_doc` may not be `NULL`.

The `None` Object

Note that the **`PyTypeObject`** for `None` is not directly exposed in the Python/C API. Since `None` is a singleton, testing for object identity (using `==` in C) is sufficient. There is no **`PyNone_Check()`** function for the same reason.

PyObject *Py_None

The Python `None` object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning **`Py_None`** from within a C function (that is, increment the reference count of `None` and return it.)

Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

On error, most `PyLong_As*` APIs return `(return type)-1` which cannot be distinguished from a number. Use **`PyErr_Occurred()`** to disambiguate.

type PyLongObject

> *Part of the Limited API (as an opaque struct).*
> This subtype of **`PyObject`** represents a Python integer object.

PyTypeObject PyLong_Type

> *Part of the Stable ABI.*
> This instance of **`PyTypeObject`** represents the Python integer type. This is the same object as **`int`** in the Python layer.

int PyLong_Check(PyObject *p)

> Return true if its argument is a **`PyLongObject`** or a subtype of **`PyLongObject`**. This function always succeeds.

int PyLong_CheckExact(PyObject *p)

> Return true if its argument is a **`PyLongObject`**, but not a subtype of **`PyLongObject`**. This function always succeeds.

PyObject *PyLong_FromLong(long v)

> *Return value: New reference. Part of the Stable ABI.*
> Return a new **`PyLongObject`** object from *v*, or `NULL` on failure.
>
> The current implementation keeps an array of integer objects

for all integers between `-5` and `256`. When you create an int in that range you actually just get back a reference to the existing object.

PyObject *PyLong_FromUnsignedLong(unsigned long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C unsigned long, or `NULL` on failure.

PyObject *PyLong_FromSsize_t(Py_ssize_t v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C **`Py_ssize_t`**, or `NULL` on failure.

PyObject *PyLong_FromSize_t(size_t v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C **`size_t`**, or `NULL` on failure.

PyObject *PyLong_FromLongLong(long long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C long long, or `NULL` on failure.

PyObject *PyLong_FromUnsignedLongLong(unsigned long long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C unsigned long long, or `NULL` on failure.

PyObject *PyLong_FromDouble(double v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from the integer part of *v*, or `NULL` on failure.

PyObject *PyLong_FromString(const char *str, char **pend, int base)

Return value: New reference. Part of the Stable ABI.
Return a new **PyLongObject** based on the string value in *str*, which is interpreted according to the radix in *base*. If *pend* is non-NULL, **pend* will point to the first character in *str* which follows the representation of the number. If *base* is 0, *str* is interpreted using the Integer literals definition; in this case, leading zeros in a non-zero decimal number raises a **ValueError**. If *base* is not 0, it must be between 2 and 36, inclusive. Leading spaces and single underscores after a base specifier and between digits are ignored. If there are no digits, **ValueError** will be raised.

PyObject *PyLong_FromUnicodeObject(PyObject *u, int base)

Return value: New reference.
Convert a sequence of Unicode digits in the string *u* to a Python integer value.

New in version 3.3.

PyObject *PyLong_FromVoidPtr(void *p)

Return value: New reference. Part of the Stable ABI.
Create a Python integer from the pointer *p*. The pointer value can be retrieved from the resulting value using **PyLong_AsVoidPtr()**.

long PyLong_AsLong(PyObject *obj)

Part of the Stable ABI.
Return a C long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

Raise **OverflowError** if the value of *obj* is out of range for a long.

Returns -1 on error. Use **PyErr_Occurred()** to disambiguate.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

long PyLong_AsLongAndOverflow(PyObject *obj, int *overflow)

Part of the Stable ABI.
Return a C long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

If the value of *obj* is greater than **LONG_MAX** or less than **LONG_MIN**, set **overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set **overflow* to `0`. If any other exception occurs set **overflow* to `0` and return `-1` as usual.

Returns `-1` on error. Use **PyErr_Occurred()** to disambiguate.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

long long PyLong_AsLongLong(PyObject *obj)

Part of the Stable ABI.
Return a C long long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

Raise **OverflowError** if the value of *obj* is out of range for a long long.

Returns `-1` on error. Use **PyErr_Occurred()** to disambiguate.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

long long PyLong_AsLongLongAndOverflow(PyObject *obj, int

*overflow)

Part of the Stable ABI.
Return a C long long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

If the value of *obj* is greater than **LLONG_MAX** or less than **LLONG_MIN**, set **overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set **overflow* to `0`. If any other exception occurs set **overflow* to `0` and return `-1` as usual.

Returns `-1` on error. Use **PyErr_Occurred()** to disambiguate.

New in version 3.2.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)

Part of the Stable ABI.
Return a C **Py_ssize_t** representation of *pylong*. *pylong* must be an instance of **PyLongObject**.

Raise **OverflowError** if the value of *pylong* is out of range for a **Py_ssize_t**.

Returns `-1` on error. Use **PyErr_Occurred()** to disambiguate.

unsigned long PyLong_AsUnsignedLong(PyObject *pylong)

Part of the Stable ABI.
Return a C unsigned long representation of *pylong*. *pylong* must be an instance of **PyLongObject**.

Raise **OverflowError** if the value of *pylong* is out of range for a unsigned long.

Returns `(unsigned long)-1` on error. Use **PyErr_Occurred()** to disambiguate.

size_t PyLong_AsSize_t(PyObject *pylong)

Part of the Stable ABI.
Return a C **size_t** representation of *pylong*. *pylong* must be an instance of **PyLongObject**.

Raise **OverflowError** if the value of *pylong* is out of range for a **size_t**.

Returns `(size_t)-1` on error. Use **PyErr_Occurred()** to disambiguate.

unsigned long long PyLong_AsUnsignedLongLong(PyObject *pylong)

Part of the Stable ABI.
Return a C unsigned long long representation of *pylong*. *pylong* must be an instance of **PyLongObject**.

Raise **OverflowError** if the value of *pylong* is out of range for an unsigned long long.

Returns `(unsigned long long)-1` on error. Use **PyErr_Occurred()** to disambiguate.

Changed in version 3.1: A negative *pylong* now raises **OverflowError**, not **TypeError**.

unsigned long PyLong_AsUnsignedLongMask(PyObject *obj)

Part of the Stable ABI.
Return a C unsigned long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

If the value of *obj* is out of range for an unsigned long, return the reduction of that value modulo `ULONG_MAX + 1`.

Returns `(unsigned long)-1` on error. Use

PyErr_Occurred() to disambiguate.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

unsigned long long PyLong_AsUnsignedLongLongMask(PyObject *obj)

Part of the Stable ABI.
Return a C unsigned long long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **__index__()** method (if present) to convert it to a **PyLongObject**.

If the value of *obj* is out of range for an unsigned long long, return the reduction of that value modulo `ULLONG_MAX + 1`.

Returns `(unsigned long long)-1` on error. Use **PyErr_Occurred()** to disambiguate.

Changed in version 3.8: Use **__index__()** if available.

Changed in version 3.10: This function will no longer use **__int__()**.

double PyLong_AsDouble(PyObject *pylong)

Part of the Stable ABI.
Return a C double representation of *pylong*. *pylong* must be an instance of **PyLongObject**.

Raise **OverflowError** if the value of *pylong* is out of range for a double.

Returns `-1.0` on error. Use **PyErr_Occurred()** to disambiguate.

void *PyLong_AsVoidPtr(PyObject *pylong)

Part of the Stable ABI.
Convert a Python integer *pylong* to a C void pointer. If *pylong* cannot be converted, an **OverflowError** will be raised. This is only assured to produce a usable void pointer for values created with **PyLong_FromVoidPtr()**.

Returns NULL on error. Use **PyErr_Occurred()** to disambiguate.

Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, **`Py_False`** and **`Py_True`**. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

int PyBool_Check(PyObject *o)

Return true if *o* is of type **`PyBool_Type`**. This function always succeeds.

PyObject *Py_False

The Python `False` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

PyObject *Py_True

The Python `True` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_FALSE

Return **`Py_False`** from a function, properly incrementing its reference count.

Py_RETURN_TRUE

Return **`Py_True`** from a function, properly incrementing its reference count.

PyObject *PyBool_FromLong(long v)

Return value: New reference. Part of the Stable ABI.
Return a new reference to **`Py_True`** or **`Py_False`** depending on the truth value of *v*.

Floating Point Objects

type PyFloatObject

This subtype of **PyObject** represents a Python floating point object.

PyTypeObject PyFloat_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python floating point type. This is the same object as **float** in the Python layer.

int PyFloat_Check(PyObject *p)

Return true if its argument is a **PyFloatObject** or a subtype of **PyFloatObject**. This function always succeeds.

int PyFloat_CheckExact(PyObject *p)

Return true if its argument is a **PyFloatObject**, but not a subtype of **PyFloatObject**. This function always succeeds.

PyObject *PyFloat_FromString(PyObject *str)

Return value: New reference. Part of the Stable ABI.
Create a **PyFloatObject** object based on the string value in *str*, or `NULL` on failure.

PyObject *PyFloat_FromDouble(double v)

Return value: New reference. Part of the Stable ABI.
Create a **PyFloatObject** object from *v*, or `NULL` on failure.

double PyFloat_AsDouble(PyObject *pyfloat)

Part of the Stable ABI.
Return a C double representation of the contents of *pyfloat*. If

pyfloat is not a Python floating point object but has a **`__float__()`** method, this method will first be called to convert *pyfloat* into a float. If `__float__()` is not defined then it falls back to **`__index__()`**. This method returns `-1.0` upon failure, so one should call **`PyErr_Occurred()`** to check for errors.

Changed in version 3.8: Use **`__index__()`** if available.

double PyFloat_AS_DOUBLE(PyObject *pyfloat)

Return a C double representation of the contents of *pyfloat*, but without error checking.

PyObject *PyFloat_GetInfo(void)

Return value: New reference. Part of the Stable ABI.
Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

double PyFloat_GetMax()

Part of the Stable ABI.
Return the maximum representable finite float *DBL_MAX* as C double.

double PyFloat_GetMin()

Part of the Stable ABI.
Return the minimum normalized positive float *DBL_MIN* as C double.

Pack and Unpack functions

The pack and unpack functions provide an efficient platform-independent way to store floating-point values as byte strings. The Pack routines produce a bytes string from a C double, and the Unpack routines produce a C double from such a bytes string. The suffix (2, 4 or 8) specifies the number of bytes in the bytes string.

On platforms that appear to use IEEE 754 formats these functions work by copying bits. On other platforms, the 2-byte format is identical to the IEEE 754 binary16 half-precision format, the 4-byte format (32-bit) is identical to the IEEE 754 binary32 single precision format, and the 8-byte format to the IEEE 754 binary64 double precision format, although the packing of INFs and NaNs (if such things exist on the platform) isn't handled correctly, and attempting to unpack a bytes string containing an IEEE INF or NaN will raise an exception.

On non-IEEE platforms with more precision, or larger dynamic range, than IEEE 754 supports, not all values can be packed; on non-IEEE platforms with less precision, or smaller dynamic range, not all values can be unpacked. What happens in such cases is partly accidental (alas).

New in version 3.11.

Pack functions

The pack routines write 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if you want the bytes string in little-endian format (exponent last, at `p+1`, `p+3`, or `p+6` `p+7`), zero if you want big-endian format (exponent first, at *p*). The **`PY_BIG_ENDIAN`** constant can be used to use the native endian: it is equal to `1` on big endian processor, or `0` on little endian processor.

Return value: `0` if all is OK, `-1` if error (and an exception is set, most likely **`OverflowError`**).

There are two problems on non-IEEE platforms:

- What this does is undefined if *x* is a NaN or infinity.
- `-0.0` and `+0.0` produce the same bytes string.

int PyFloat_Pack2(double x, unsigned char *p, int le)

Pack a C double as the IEEE 754 binary16 half-precision format.

int PyFloat_Pack4(double x, unsigned char *p, int le)

Pack a C double as the IEEE 754 binary32 single precision format.

int PyFloat_Pack8(double x, unsigned char *p, int le)

Pack a C double as the IEEE 754 binary64 double precision format.

Unpack functions

The unpack routines read 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if the bytes string is in little-endian format (exponent last, at `p+1`, `p+3` or `p+6` and `p+7`), zero if big-endian (exponent first, at *p*). The **`PY_BIG_ENDIAN`** constant can be used to use the native endian: it is equal to `1` on big endian processor, or `0` on little endian processor.

Return value: The unpacked double. On error, this is `-1.0` and **`PyErr_Occurred()`** is true (and an exception is set, most likely **`OverflowError`**).

Note that on a non-IEEE platform this will refuse to unpack a bytes string that represents a NaN or infinity.

double PyFloat_Unpack2(const unsigned char *p, int le)

Unpack the IEEE 754 binary16 half-precision format as a C double.

double PyFloat_Unpack4(const unsigned char *p, int le)

Unpack the IEEE 754 binary32 single precision format as a C double.

double PyFloat_Unpack8(const unsigned char *p, int le)

Unpack the IEEE 754 binary64 double precision format as a C double.

Complex Number Objects

Python's complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so *by value* rather than dereferencing them through pointers. This is consistent throughout the API.

type Py_complex

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```
typedef struct {
   double real;
   double imag;
} Py_complex;
```

Py_complex _Py_c_sum(Py_complex left, Py_complex right)

Return the sum of two complex numbers, using the C **`Py_complex`** representation.

Py_complex _Py_c_diff(Py_complex left, Py_complex right)

Return the difference between two complex numbers, using the C **`Py_complex`** representation.

Py_complex _Py_c_neg(Py_complex num)

Return the negation of the complex number *num*, using the C **Py_complex** representation.

Py_complex _Py_c_prod(Py_complex left, Py_complex right)

Return the product of two complex numbers, using the C **Py_complex** representation.

Py_complex _Py_c_quot(Py_complex dividend, Py_complex divisor)

Return the quotient of two complex numbers, using the C **Py_complex** representation.

If *divisor* is null, this method returns zero and sets **errno** to **EDOM**.

Py_complex _Py_c_pow(Py_complex num, Py_complex exp)

Return the exponentiation of *num* by *exp*, using the C **Py_complex** representation.

If *num* is null and *exp* is not a positive real number, this method returns zero and sets **errno** to **EDOM**.

Complex Numbers as Python Objects

type PyComplexObject

This subtype of **PyObject** represents a Python complex number object.

PyTypeObject PyComplex_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python complex number type. It is the same object as **complex** in the Python layer.

int PyComplex_Check(PyObject *p)

Return true if its argument is a **PyComplexObject** or a subtype of **PyComplexObject**. This function always succeeds.

int PyComplex_CheckExact(PyObject *p)

Return true if its argument is a **PyComplexObject**, but not a subtype of **PyComplexObject**. This function always succeeds.

PyObject *PyComplex_FromCComplex(Py_complex v)

Return value: New reference.
Create a new Python complex number object from a C **Py_complex** value.

PyObject *PyComplex_FromDoubles(double real, double imag)

Return value: New reference. Part of the Stable ABI.
Return a new **PyComplexObject** object from *real* and *imag*.

double PyComplex_RealAsDouble(PyObject *op)

Part of the Stable ABI.
Return the real part of *op* as a C double.

double PyComplex_ImagAsDouble(PyObject *op)

Part of the Stable ABI.
Return the imaginary part of *op* as a C double.

Py_complex PyComplex_AsCComplex(PyObject *op)

Return the **Py_complex** value of the complex number *op*.

If *op* is not a Python complex number object but has a **__complex__()** method, this method will first be called to convert *op* to a Python complex number object. If `__complex__()` is not defined then it falls back to **__float__()**. If `__float__()` is not defined then it falls back to **__index__()**. Upon failure, this method returns `-1.0` as a real value.

Changed in version 3.8: Use **__index__()** if available.

Bytes Objects

These functions raise **`TypeError`** when expecting a bytes parameter and called with a non-bytes parameter.

type PyBytesObject

This subtype of **`PyObject`** represents a Python bytes object.

PyTypeObject PyBytes_Type

Part of the Stable ABI.
This instance of **`PyTypeObject`** represents the Python bytes type; it is the same object as **`bytes`** in the Python layer.

int PyBytes_Check(PyObject *o)

Return true if the object *o* is a bytes object or an instance of a subtype of the bytes type. This function always succeeds.

int PyBytes_CheckExact(PyObject *o)

Return true if the object *o* is a bytes object, but not an instance of a subtype of the bytes type. This function always succeeds.

PyObject *PyBytes_FromString(const char *v)

Return value: New reference. Part of the Stable ABI.
Return a new bytes object with a copy of the string *v* as value on success, and `NULL` on failure. The parameter *v* must not be `NULL`; it will not be checked.

PyObject *PyBytes_FromStringAndSize(const char *v, Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.
Return a new bytes object with a copy of the string *v* as value and length *len* on success, and `NULL` on failure. If *v* is `NULL`, the contents of the bytes object are uninitialized.

PyObject *PyBytes_FromFormat(const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Take a C **`printf()`**-style *format* string and a variable number of arguments, calculate the size of the resulting Python bytes object and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* string. The following format characters are allowed:

Format Characters	Type	Comment
`%%`	*n/a*	The literal % character.
`%c`	int	A single byte, represented as a C int.
`%d`	Equivalent to `printf("%d")`. [1]	
`%u`	unsigned int	Equivalent to `printf("%u")`. [1]
`%ld`	Equivalent to `printf("%ld")`. [1]	
`%lu`	unsigned long	Equivalent to `printf("%lu")`. [1]
`%zd`	Py_ssize_t	Equivalent to `printf("%zd")`. [1]
`%zu`	size_t	Equivalent to `printf("%zu")`. [1]
`%i`	int	Equivalent to `printf("%i")`. [1]
`%x`	int	Equivalent to `printf("%x")`. [1]
`%s`	const char*	A null-terminated C character array.
`%p`	const void*	The hex representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf` yields.

An unrecognized format character causes all the rest of the format string to be copied as-is to the result object, and any extra arguments discarded.

1([1](),[2](),[3](),[4](),[5](),[6](),[7](),[8]())

For integer specifiers (d, u, ld, lu, zd, zu, i, x): the 0-conversion flag has effect even when a precision is given.

PyObject *PyBytes_FromFormatV(const char *format, va_list vargs)

Return value: New reference. Part of the Stable ABI.
Identical to **`PyBytes_FromFormat()`** except that it takes exactly two arguments.

PyObject *PyBytes_FromObject(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return the bytes representation of object *o* that implements the buffer protocol.

Py_ssize_t PyBytes_Size(PyObject *o)

Part of the Stable ABI.
Return the length of the bytes in bytes object *o*.

Py_ssize_t PyBytes_GET_SIZE(PyObject *o)

Similar to **`PyBytes_Size()`**, but without error checking.

char *PyBytes_AsString(PyObject *o)

Part of the Stable ABI.
Return a pointer to the contents of *o*. The pointer refers to the internal buffer of *o*, which consists of `len(o) + 1` bytes. The last byte in the buffer is always null, regardless of whether there are any other null bytes. The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *o* is not a bytes object at all, **`PyBytes_AsString()`** returns `NULL` and raises **`TypeError`**.

char *PyBytes_AS_STRING(PyObject *string)

Similar to **`PyBytes_AsString()`**, but without error checking.

int PyBytes_AsStringAndSize(PyObject *obj, char **buffer, Py_ssize_t *length)

Part of the Stable ABI.
Return the null-terminated contents of the object *obj* through the output variables *buffer* and *length*.

If *length* is `NULL`, the bytes object may not contain embedded null bytes; if it does, the function returns `-1` and a **`ValueError`** is raised.

The buffer refers to an internal buffer of *obj*, which includes an additional null byte at the end (not counted in *length*). The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *obj* is not a bytes object at all, **`PyBytes_AsStringAndSize()`** returns `-1` and raises **`TypeError`**.

Changed in version 3.5: Previously, **`TypeError`** was raised when embedded null bytes were encountered in the bytes object.

void PyBytes_Concat(PyObject **bytes, PyObject *newpart)

Part of the Stable ABI.
Create a new bytes object in **bytes* containing the contents of *newpart* appended to *bytes*; the caller will own the new reference. The reference to the old value of *bytes* will be stolen. If the new object cannot be created, the old reference to *bytes* will still be discarded and the value of **bytes* will be set to `NULL`; the appropriate exception will be set.

void PyBytes_ConcatAndDel(PyObject **bytes, PyObject *newpart)

Part of the Stable ABI.
Create a new bytes object in **bytes* containing the contents of *newpart* appended to *bytes*. This version decrements the reference count of *newpart*.

int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)

A way to resize a bytes object even though it is “immutable”. Only use this to build up a brand new bytes object; don’t use this if the bytes may already be known in other parts of the code. It is an error to call this function if the refcount on the input bytes object is not one. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, **bytes* holds the resized bytes object and `0` is returned; the address in **bytes* may differ from its input value. If the reallocation fails, the original bytes object at **bytes* is deallocated, **bytes* is set to `NULL`,

MemoryError is set, and `-1` is returned.

Byte Array Objects

type PyByteArrayObject

This subtype of **`PyObject`** represents a Python bytearray object.

PyTypeObject PyByteArray_Type

Part of the Stable ABI.
This instance of **`PyTypeObject`** represents the Python bytearray type; it is the same object as **`bytearray`** in the Python layer.

Type check macros

int PyByteArray_Check(PyObject *o)

Return true if the object *o* is a bytearray object or an instance of a subtype of the bytearray type. This function always succeeds.

int PyByteArray_CheckExact(PyObject *o)

Return true if the object *o* is a bytearray object, but not an instance of a subtype of the bytearray type. This function always succeeds.

Direct API functions

PyObject *PyByteArray_FromObject(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return a new bytearray object from any object, *o*, that implements the buffer protocol.

PyObject *PyByteArray_FromStringAndSize(const char *string,

Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.
Create a new bytearray object from *string* and its length, *len*. On failure, `NULL` is returned.

PyObject *PyByteArray_Concat(PyObject *a, PyObject *b)

Return value: New reference. Part of the Stable ABI.
Concat bytearrays *a* and *b* and return a new bytearray with the result.

Py_ssize_t PyByteArray_Size(PyObject *bytearray)

Part of the Stable ABI.
Return the size of *bytearray* after checking for a `NULL` pointer.

char *PyByteArray_AsString(PyObject *bytearray)

Part of the Stable ABI.
Return the contents of *bytearray* as a char array after checking for a `NULL` pointer. The returned array always has an extra null byte appended.

int PyByteArray_Resize(PyObject *bytearray, Py_ssize_t len)

Part of the Stable ABI.
Resize the internal buffer of *bytearray* to *len*.

Macros

These macros trade safety for speed and they don't check pointers.

char *PyByteArray_AS_STRING(PyObject *bytearray)

Similar to **`PyByteArray_AsString()`**, but without error checking.

Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)

Similar to **`PyByteArray_Size()`**, but without error checking.

Unicode Objects and Codecs

Unicode Objects

Since the implementation of **PEP 393** [https://peps.python.org/pep-0393/] in Python 3.3, Unicode objects internally use a variety of representations, in order to allow handling the complete range of Unicode characters while staying memory efficient. There are special cases for strings where all code points are below 128, 256, or 65536; otherwise, code points must be below 1114112 (which is the full Unicode range).

Py_UNICODE* and UTF-8 representations are created on demand and cached in the Unicode object. The Py_UNICODE* representation is deprecated and inefficient.

Due to the transition between the old APIs and the new APIs, Unicode objects can internally be in two states depending on how they were created:

- "canonical" Unicode objects are all objects created by a non-deprecated Unicode API. They use the most efficient representation allowed by the implementation.
- "legacy" Unicode objects have been created through one of the deprecated APIs (typically **`PyUnicode_FromUnicode()`**) and only bear the Py_UNICODE* representation; you will have to call **`PyUnicode_READY()`** on them before calling any other API.

Note

The "legacy" Unicode object will be removed in Python 3.12 with deprecated APIs. All Unicode objects will be "canonical" since then. See **PEP 623** [https://peps.python.org/pep-0623/] for more information.

Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

type Py_UCS4
type Py_UCS2
type Py_UCS1

Part of the Stable ABI.
These types are typedefs for unsigned integer types wide enough to contain characters of 32 bits, 16 bits and 8 bits, respectively. When dealing with single Unicode characters, use **Py_UCS4**.

New in version 3.3.

type Py_UNICODE

This is a typedef of wchar_t, which is a 16-bit type or 32-bit type depending on the platform.

Changed in version 3.3: In previous versions, this was a 16-bit type or a 32-bit type depending on whether you selected a "narrow" or "wide" Unicode version of Python at build time.

type PyASCIIObject
type PyCompactUnicodeObject
type PyUnicodeObject

These subtypes of **PyObject** represent a Python Unicode object. In almost all cases, they shouldn't be used directly, since all API functions that deal with Unicode objects take and return **PyObject** pointers.

New in version 3.3.

PyTypeObject PyUnicode_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python Unicode type. It is exposed to Python code as `str`.

The following APIs are C macros and static inlined functions for fast checks and access to internal read-only data of Unicode objects:

int PyUnicode_Check(PyObject *o)

Return true if the object *o* is a Unicode object or an instance of a Unicode subtype. This function always succeeds.

int PyUnicode_CheckExact(PyObject *o)

Return true if the object *o* is a Unicode object, but not an instance of a subtype. This function always succeeds.

int PyUnicode_READY(PyObject *o)

Ensure the string object *o* is in the "canonical" representation. This is required before using any of the access macros described below.

Returns `0` on success and `-1` with an exception set on failure, which in particular happens if memory allocation fails.

New in version 3.3.

Deprecated since version 3.10, will be removed in version 3.12: This API will be removed with **`PyUnicode_FromUnicode()`**.

Py_ssize_t PyUnicode_GET_LENGTH(PyObject *o)

Return the length of the Unicode string, in code points. *o* has to be a Unicode object in the "canonical" representation (not checked).

New in version 3.3.

Py_UCS1 *PyUnicode_1BYTE_DATA(PyObject *o)
Py_UCS2 *PyUnicode_2BYTE_DATA(PyObject *o)
Py_UCS4 *PyUnicode_4BYTE_DATA(PyObject *o)

Return a pointer to the canonical representation cast to UCS1, UCS2 or UCS4 integer types for direct character access. No

checks are performed if the canonical representation has the correct character size; use **PyUnicode_KIND()** to select the right macro. Make sure **PyUnicode_READY()** has been called before accessing this.

New in version 3.3.

PyUnicode_WCHAR_KIND
PyUnicode_1BYTE_KIND
PyUnicode_2BYTE_KIND
PyUnicode_4BYTE_KIND

Return values of the **PyUnicode_KIND()** macro.

New in version 3.3.

Deprecated since version 3.10, will be removed in version 3.12: `PyUnicode_WCHAR_KIND` is deprecated.

int PyUnicode_KIND(PyObject *o)

Return one of the PyUnicode kind constants (see above) that indicate how many bytes per character this Unicode object uses to store its data. *o* has to be a Unicode object in the "canonical" representation (not checked).

New in version 3.3.

void *PyUnicode_DATA(PyObject *o)

Return a void pointer to the raw Unicode buffer. *o* has to be a Unicode object in the "canonical" representation (not checked).

New in version 3.3.

void PyUnicode_WRITE(int kind, void *data, Py_ssize_t index, Py_UCS4 value)

Write into a canonical representation *data* (as obtained with **PyUnicode_DATA()**). This function performs no sanity checks, and is intended for usage in loops. The caller should cache the *kind* value and *data* pointer as obtained from other

calls. *index* is the index in the string (starts at 0) and *value* is the new code point value which should be written to that location.

New in version 3.3.

Py_UCS4 PyUnicode_READ(int kind, void *data, Py_ssize_t index)

Read a code point from a canonical representation *data* (as obtained with **PyUnicode_DATA()**). No checks or ready calls are performed.

New in version 3.3.

Py_UCS4 PyUnicode_READ_CHAR(PyObject *o, Py_ssize_t index)

Read a character from a Unicode object *o*, which must be in the "canonical" representation. This is less efficient than **PyUnicode_READ()** if you do multiple consecutive reads.

New in version 3.3.

Py_UCS4 PyUnicode_MAX_CHAR_VALUE(PyObject *o)

Return the maximum code point that is suitable for creating another string based on *o*, which must be in the "canonical" representation. This is always an approximation but more efficient than iterating over the string.

New in version 3.3.

Py_ssize_t PyUnicode_GET_SIZE(PyObject *o)

Return the size of the deprecated **Py_UNICODE** representation, in code units (this includes surrogate pairs as 2 units). *o* has to be a Unicode object (not checked).

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **PyUnicode_GET_LENGTH()**.

Py_ssize_t PyUnicode_GET_DATA_SIZE(PyObject *o)

Return the size of the deprecated **Py_UNICODE** representation in bytes. *o* has to be a Unicode object (not checked).

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **PyUnicode_GET_LENGTH()**.

Py_UNICODE *PyUnicode_AS_UNICODE(PyObject *o)
const char *PyUnicode_AS_DATA(PyObject *o)

Return a pointer to a **Py_UNICODE** representation of the object. The returned buffer is always terminated with an extra null code point. It may also contain embedded null code points, which would cause the string to be truncated when used in most C functions. The `AS_DATA` form casts the pointer to const char*. The *o* argument has to be a Unicode object (not checked).

Changed in version 3.3: This function is now inefficient – because in many cases the **Py_UNICODE** representation does not exist and needs to be created – and can fail (return `NULL` with an exception set). Try to port the code to use the new **PyUnicode_nBYTE_DATA()** macros or use **PyUnicode_WRITE()** or **PyUnicode_READ()**.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using the **PyUnicode_nBYTE_DATA()** family of macros.

int PyUnicode_IsIdentifier(PyObject *o)

Part of the Stable ABI.
Return `1` if the string is a valid identifier according to the language definition, section Identifiers and keywords. Return `0` otherwise.

Changed in version 3.9: The function does not call **Py_FatalError()** anymore if the string is not ready.

Unicode Character Properties

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

int Py_UNICODE_ISSPACE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a whitespace character.

int Py_UNICODE_ISLOWER(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a lowercase character.

int Py_UNICODE_ISUPPER(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an uppercase character.

int Py_UNICODE_ISTITLE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a titlecase character.

int Py_UNICODE_ISLINEBREAK(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a linebreak character.

int Py_UNICODE_ISDECIMAL(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a decimal character.

int Py_UNICODE_ISDIGIT(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a digit character.

int Py_UNICODE_ISNUMERIC(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a numeric character.

int Py_UNICODE_ISALPHA(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an alphabetic character.

int Py_UNICODE_ISALNUM(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an alphanumeric character.

int Py_UNICODE_ISPRINTABLE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a printable character. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when **`repr()`** is invoked on a string. It has no bearing on the handling of strings written to **`sys.stdout`** or **`sys.stderr`**.)

These APIs can be used for fast direct character conversions:

Py_UCS4 Py_UNICODE_TOLOWER(Py_UCS4 ch)

Return the character *ch* converted to lower case.

Deprecated since version 3.3: This function uses simple case mappings.

Py_UCS4 Py_UNICODE_TOUPPER(Py_UCS4 ch)

Return the character *ch* converted to upper case.

Deprecated since version 3.3: This function uses simple case mappings.

Py_UCS4 Py_UNICODE_TOTITLE(Py_UCS4 ch)

Return the character *ch* converted to title case.

Deprecated since version 3.3: This function uses simple case mappings.

int Py_UNICODE_TODECIMAL(Py_UCS4 ch)

Return the character *ch* converted to a decimal positive integer. Return `-1` if this is not possible. This macro does not raise exceptions.

int Py_UNICODE_TODIGIT(Py_UCS4 ch)

Return the character *ch* converted to a single digit integer. Return `-1` if this is not possible. This macro does not raise exceptions.

double Py_UNICODE_TONUMERIC(Py_UCS4 ch)

Return the character *ch* converted to a double. Return `-1.0` if this is not possible. This macro does not raise exceptions.

These APIs can be used to work with surrogates:

Py_UNICODE_IS_SURROGATE(ch)

Check if *ch* is a surrogate (`0xD800 <= ch <= 0xDFFF`).

Py_UNICODE_IS_HIGH_SURROGATE(ch)

Check if *ch* is a high surrogate (`0xD800 <= ch <= 0xDBFF`).

Py_UNICODE_IS_LOW_SURROGATE(ch)

Check if *ch* is a low surrogate (`0xDC00 <= ch <= 0xDFFF`).

Py_UNICODE_JOIN_SURROGATES(high, low)

Join two surrogate characters and return a single Py_UCS4 value. *high* and *low* are respectively the leading and trailing surrogates in a surrogate pair.

Creating and accessing Unicode strings

To create Unicode objects and access their basic sequence properties, use these APIs:

PyObject *PyUnicode_New(Py_ssize_t size, Py_UCS4 maxchar)

Return value: New reference.
Create a new Unicode object. *maxchar* should be the true maximum code point to be placed in the string. As an approximation, it can be rounded up to the nearest value in the sequence 127, 255, 65535, 1114111.

This is the recommended way to allocate a new Unicode object. Objects created using this function are not resizable.

New in version 3.3.

PyObject *PyUnicode_FromKindAndData(int kind, const void *buffer, Py_ssize_t size)

Return value: New reference.
Create a new Unicode object with the given *kind* (possible values are **PyUnicode_1BYTE_KIND** etc., as returned by **PyUnicode_KIND()**). The *buffer* must point to an array of *size* units of 1, 2 or 4 bytes per character, as given by the kind.

If necessary, the input *buffer* is copied and transformed into the canonical representation. For example, if the *buffer* is a UCS4 string (**PyUnicode_4BYTE_KIND**) and it consists only of codepoints in the UCS1 range, it will be transformed into UCS1 (**PyUnicode_1BYTE_KIND**).

New in version 3.3.

PyObject *PyUnicode_FromStringAndSize(const char *u, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object from the char buffer *u*. The bytes will be interpreted as being UTF-8 encoded. The buffer is copied into the new object. If the buffer is not `NULL`, the return value might be a shared object, i.e. modification of the data is not allowed.

If *u* is `NULL`, this function behaves like

PyUnicode_FromUnicode() with the buffer set to `NULL`. This usage is deprecated in favor of **PyUnicode_New()**, and will be removed in Python 3.12.

PyObject *PyUnicode_FromString(const char *u)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object from a UTF-8 encoded null-terminated char buffer *u*.

PyObject *PyUnicode_FromFormat(const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Take a C **printf()**-style *format* string and a variable number of arguments, calculate the size of the resulting Python Unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* ASCII-encoded string. The following format characters are allowed:

Format Characters	Type	Comment
%%	n/a	The literal % character.
%c	int	A single character, represented as a C int.
%d	Equivalent to `printf("%d")`. [1]	
%u	Equivalent to `printf("%u")`. [1]	
%ld	Equivalent to `printf("%ld")`. [1]	
%li	Equivalent to `printf("%li")`. [1]	
%lu	Equivalent to `printf("%lu")`. [1]	
%lld	Equivalent to `printf("%lld")`. [1]	
%lli	Equivalent to `printf("%lli")`. [1]	
%llu	Equivalent to `printf("%llu")`. [1]	
%zd	Equivalent to `printf("%zd")`. [1]	
%zi	Equivalent to `printf("%zi")`. [1]	
%zu	Equivalent to `printf("%zu")`. [1]	
%i	Equivalent to `printf("%i")`. [1]	
%x	Equivalent to `printf("%x")`. [1]	
%s	const char*	A null-terminated C character array.
%p	const void*	The hex representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf`

yields.

The result of calling **`ascii()`**.	
A Unicode object.	
A Unicode object (which may be `NULL`) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is `NULL`).	
The result of calling **`PyObject_Str()`**.	
The result of calling **`PyObject_Repr()`**.	

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

Note

The width formatter unit is number of characters rather than bytes. The precision formatter unit is number of bytes for `"%s"` and `"%V"` (if the `PyObject*` argument is `NULL`), and a number of characters for `"%A"`, `"%U"`, `"%S"`, `"%R"` and `"%V"` (if the `PyObject*` argument is not `NULL`).

1(*1*,*2*,*3*,*4*,*5*,*6*,*7*,*8*,*9*,*10*,*11*,*12*,*13*)

For integer specifiers (d, u, ld, li, lu, lld, lli, llu, zd, zi, zu, i, x): the 0-conversion flag has effect even when a precision is given.

Changed in version 3.2: Support for `"%lld"` and `"%llu"` added.

Changed in version 3.3: Support for `"%li"`, `"%lli"` and `"%zi"` added.

Changed in version 3.4: Support width and precision formatter for `"%s"`, `"%A"`, `"%U"`, `"%V"`, `"%S"`, `"%R"` added.

PyObject *PyUnicode_FromFormatV(const char *format, va_list vargs)

Return value: New reference. Part of the Stable ABI.

Identical to **PyUnicode_FromFormat()** except that it takes exactly two arguments.

PyObject *PyUnicode_FromEncodedObject(PyObject *obj, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Decode an encoded object *obj* to a Unicode object.

bytes, **bytearray** and other bytes-like objects are decoded according to the given *encoding* and using the error handling defined by *errors*. Both can be `NULL` to have the interface use the default values (see Built-in Codecs for details).

All other objects, including Unicode objects, cause a **TypeError** to be set.

The API returns `NULL` if there was an error. The caller is responsible for decref'ing the returned objects.

Py_ssize_t PyUnicode_GetLength(PyObject *unicode)

Part of the Stable ABI since version 3.7.
Return the length of the Unicode object, in code points.

New in version 3.3.

Py_ssize_t PyUnicode_CopyCharacters(PyObject *to, Py_ssize_t to_start, PyObject *from, Py_ssize_t from_start, Py_ssize_t how_many)

Copy characters from one Unicode object into another. This function performs character conversion when necessary and falls back to **memcpy()** if possible. Returns `-1` and sets an exception on error, otherwise returns the number of copied characters.

New in version 3.3.

Py_ssize_t PyUnicode_Fill(PyObject *unicode, Py_ssize_t start, Py_ssize_t length, Py_UCS4 fill_char)

Fill a string with a character: write *fill_char* into

`unicode[start:start+length]`.

Fail if *fill_char* is bigger than the string maximum character, or if the string has more than 1 reference.

Return the number of written character, or return `-1` and raise an exception on error.

New in version 3.3.

int PyUnicode_WriteChar(PyObject *unicode, Py_ssize_t index, Py_UCS4 character)

Part of the Stable ABI since version 3.7.
Write a character to a string. The string must have been created through **`PyUnicode_New()`**. Since Unicode strings are supposed to be immutable, the string must not be shared, or have been hashed yet.

This function checks that *unicode* is a Unicode object, that the index is not out of bounds, and that the object can be modified safely (i.e. that it its reference count is one).

New in version 3.3.

Py_UCS4 PyUnicode_ReadChar(PyObject *unicode, Py_ssize_t index)

Part of the Stable ABI since version 3.7.
Read a character from a string. This function checks that *unicode* is a Unicode object and the index is not out of bounds, in contrast to **`PyUnicode_READ_CHAR()`**, which performs no error checking.

New in version 3.3.

PyObject *PyUnicode_Substring(PyObject *str, Py_ssize_t start, Py_ssize_t end)

Return value: New reference. Part of the Stable ABI since version 3.7.
Return a substring of *str*, from character index *start* (included) to character index *end* (excluded). Negative indices are not

supported.

New in version 3.3.

Py_UCS4 *PyUnicode_AsUCS4(PyObject *u, Py_UCS4 *buffer, Py_ssize_t buflen, int copy_null)

Part of the Stable ABI since version 3.7.
Copy the string *u* into a UCS4 buffer, including a null character, if *copy_null* is set. Returns `NULL` and sets an exception on error (in particular, a **`SystemError`** if *buflen* is smaller than the length of *u*). *buffer* is returned on success.

New in version 3.3.

Py_UCS4 *PyUnicode_AsUCS4Copy(PyObject *u)

Part of the Stable ABI since version 3.7.
Copy the string *u* into a new UCS4 buffer that is allocated using **`PyMem_Malloc()`**. If this fails, `NULL` is returned with a **`MemoryError`** set. The returned buffer always has an extra null code point appended.

New in version 3.3.

Deprecated Py_UNICODE APIs

Deprecated since version 3.3, will be removed in version 3.12.

These API functions are deprecated with the implementation of **PEP 393** [https://peps.python.org/pep-0393/]. Extension modules can continue using them, as they will not be removed in Python 3.x, but need to be aware that their use can now cause performance and memory hits.

PyObject *PyUnicode_FromUnicode(const Py_UNICODE *u, Py_ssize_t size)

Return value: New reference.
Create a Unicode object from the Py_UNICODE buffer *u* of the given size. *u* may be `NULL` which causes the contents to be undefined. It is the user's responsibility to fill in the needed

data. The buffer is copied into the new object.

If the buffer is not `NULL`, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when *u* is `NULL`.

If the buffer is `NULL`, **`PyUnicode_READY()`** must be called once the string content has been filled before using any of the access macros such as **`PyUnicode_KIND()`**.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **`PyUnicode_FromKindAndData()`**, **`PyUnicode_FromWideChar()`**, or **`PyUnicode_New()`**.

Py_UNICODE *PyUnicode_AsUnicode(PyObject *unicode)

Return a read-only pointer to the Unicode object's internal **`Py_UNICODE`** buffer, or `NULL` on error. This will create the Py_UNICODE* representation of the object if it is not yet available. The buffer is always terminated with an extra null code point. Note that the resulting **`Py_UNICODE`** string may also contain embedded null code points, which would cause the string to be truncated when used in most C functions.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **`PyUnicode_AsUCS4()`**, **`PyUnicode_AsWideChar()`**, **`PyUnicode_ReadChar()`** or similar new APIs.

Py_UNICODE *PyUnicode_AsUnicodeAndSize(PyObject *unicode, Py_ssize_t *size)

Like **`PyUnicode_AsUnicode()`**, but also saves the **`Py_UNICODE()`** array length (excluding the extra null terminator) in *size*. Note that the resulting Py_UNICODE* string may contain embedded null code points, which would cause the string to be truncated when used in most C functions.

New in version 3.3.

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **PyUnicode_AsUCS4()**, **PyUnicode_AsWideChar()**, **PyUnicode_ReadChar()** or similar new APIs.

Py_ssize_t PyUnicode_GetSize(PyObject *unicode)

Part of the Stable ABI.
Return the size of the deprecated **Py_UNICODE** representation, in code units (this includes surrogate pairs as 2 units).

Deprecated since version 3.3, will be removed in version 3.12: Part of the old-style Unicode API, please migrate to using **PyUnicode_GET_LENGTH()**.

PyObject *PyUnicode_FromObject(PyObject *obj)

Return value: New reference. Part of the Stable ABI.
Copy an instance of a Unicode subtype to a new true Unicode object if necessary. If *obj* is already a true Unicode object (not a subtype), return the reference with incremented refcount.

Objects other than Unicode or its subtypes will cause a **TypeError**.

Locale Encoding

The current locale encoding can be used to decode text from the operating system.

PyObject *PyUnicode_DecodeLocaleAndSize(const char *str, Py_ssize_t len, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Decode a string from UTF-8 on Android and VxWorks, or from the current locale encoding on other platforms. The supported error handlers are `"strict"` and `"surrogateescape"` (**PEP 383** [https://peps.python.org/pep-0383/]). The decoder uses `"strict"` error handler if

errors is `NULL`. *str* must end with a null character but cannot contain embedded null characters.

Use **`PyUnicode_DecodeFSDefaultAndSize()`** to decode a string from **`Py_FileSystemDefaultEncoding`** (the locale encoding read at Python startup).

This function ignores the Python UTF-8 Mode.

See also

The **`Py_DecodeLocale()`** function.

New in version 3.3.

Changed in version 3.7: The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, **`Py_DecodeLocale()`** was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

PyObject *PyUnicode_DecodeLocale(const char *str, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Similar to **`PyUnicode_DecodeLocaleAndSize()`**, but compute the string length using **`strlen()`**.

New in version 3.3.

PyObject *PyUnicode_EncodeLocale(PyObject *unicode, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Encode a Unicode object to UTF-8 on Android and VxWorks, or to the current locale encoding on other platforms. The supported error handlers are `"strict"` and `"surrogateescape"` (**PEP 383** [https://peps.python.org/pep-0383/]). The encoder uses `"strict"` error handler if

errors is `NULL`. Return a **bytes** object. *unicode* cannot contain embedded null characters.

Use **PyUnicode_EncodeFSDefault()** to encode a string to **Py_FileSystemDefaultEncoding** (the locale encoding read at Python startup).

This function ignores the Python UTF-8 Mode.

See also

The **Py_EncodeLocale()** function.

New in version 3.3.

Changed in version 3.7: The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, **Py_EncodeLocale()** was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

File System Encoding

To encode and decode file names and other environment strings, **Py_FileSystemDefaultEncoding** should be used as the encoding, and **Py_FileSystemDefaultEncodeErrors** should be used as the error handler (**PEP 383** [https://peps.python.org/pep-0383/] and **PEP 529** [https://peps.python.org/pep-0529/]). To encode file names to **bytes** during argument parsing, the `"O&"` converter should be used, passing **PyUnicode_FSConverter()** as the conversion function:

int PyUnicode_FSConverter(PyObject *obj, void *result)

Part of the Stable ABI.
ParseTuple converter: encode **str** objects – obtained directly or through the **os.PathLike** interface – to **bytes** using **PyUnicode_EncodeFSDefault()**; **bytes** objects are output as-is. *result* must be a PyBytesObject* which must be released when it is no longer used.

New in version 3.1.

Changed in version 3.6: Accepts a path-like object.

To decode file names to **str** during argument parsing, the `"O&"` converter should be used, passing **PyUnicode_FSDecoder()** as the conversion function:

int PyUnicode_FSDecoder(PyObject *obj, void *result)

Part of the Stable ABI.
ParseTuple converter: decode **bytes** objects – obtained either directly or indirectly through the **os.PathLike** interface – to **str** using **PyUnicode_DecodeFSDefaultAndSize()**; **str** objects are output as-is. *result* must be a PyUnicodeObject* which must be released when it is no longer used.

New in version 3.2.

Changed in version 3.6: Accepts a path-like object.

PyObject *PyUnicode_DecodeFSDefaultAndSize(const char *s, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.
Decode a string from the filesystem encoding and error handler.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Py_FileSystemDefaultEncoding is initialized at startup from the locale encoding and cannot be modified later. If you need to decode a string from the current locale encoding, use **PyUnicode_DecodeLocaleAndSize()**.

See also

The **Py_DecodeLocale()** function.

Changed in version 3.6: Use

Py_FileSystemDefaultEncodeErrors error handler.

PyObject *PyUnicode_DecodeFSDefault(const char *s)

Return value: New reference. Part of the Stable ABI.
Decode a null-terminated string from the filesystem encoding and error handler.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Use **PyUnicode_DecodeFSDefaultAndSize()** if you know the string length.

Changed in version 3.6: Use **Py_FileSystemDefaultEncodeErrors** error handler.

PyObject *PyUnicode_EncodeFSDefault(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object to **Py_FileSystemDefaultEncoding** with the **Py_FileSystemDefaultEncodeErrors** error handler, and return **bytes**. Note that the resulting **bytes** object may contain null bytes.

If **Py_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Py_FileSystemDefaultEncoding is initialized at startup from the locale encoding and cannot be modified later. If you need to encode a string to the current locale encoding, use **PyUnicode_EncodeLocale()**.

See also

The **Py_EncodeLocale()** function.

New in version 3.2.

Changed in version 3.6: Use **Py_FileSystemDefaultEncodeErrors** error handler.

wchar_t Support

wchar_t support for platforms which support it:

PyObject *PyUnicode_FromWideChar(const wchar_t *w, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object from the wchar_t buffer *w* of the given *size*. Passing `-1` as the *size* indicates that the function must itself compute the length, using wcslen. Return `NULL` on failure.

Py_ssize_t PyUnicode_AsWideChar(PyObject *unicode, wchar_t *w, Py_ssize_t size)

Part of the Stable ABI.
Copy the Unicode object contents into the wchar_t buffer *w*. At most *size* wchar_t characters are copied (excluding a possibly trailing null termination character). Return the number of wchar_t characters copied or `-1` in case of an error. Note that the resulting wchar_t* string may or may not be null-terminated. It is the responsibility of the caller to make sure that the wchar_t* string is null-terminated in case this is required by the application. Also, note that the wchar_t* string might contain null characters, which would cause the string to be truncated when used with most C functions.

wchar_t *PyUnicode_AsWideCharString(PyObject *unicode, Py_ssize_t *size)

Part of the Stable ABI since version 3.7.
Convert the Unicode object to a wide character string. The output string always ends with a null character. If *size* is not `NULL`, write the number of wide characters (excluding the trailing null termination character) into **size*. Note that the resulting wchar_t string might contain null characters, which would cause the string to be truncated when used with most C functions. If *size* is `NULL` and the wchar_t* string contains null characters a **`ValueError`** is raised.

Returns a buffer allocated by **PyMem_Alloc()** (use **PyMem_Free()** to free it) on success. On error, returns NULL and **size* is undefined. Raises a **MemoryError** if memory allocation is failed.

New in version 3.2.

Changed in version 3.7: Raises a **ValueError** if *size* is NULL and the wchar_t* string contains null characters.

Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors, and they have the same semantics as the ones of the built-in **str()** string object constructor.

Setting encoding to NULL causes the default encoding to be used which is UTF-8. The file system calls should use **PyUnicode_FSConverter()** for encoding file names. This uses the variable **Py_FileSystemDefaultEncoding** internally. This variable should be treated as read-only: on some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes setlocale).

Error handling is set by errors which may also be set to NULL meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (**ValueError** is raised).

The codecs all use a similar interface. Only deviations from the following generic ones are documented for simplicity.

Generic Codecs

These are the generic codec APIs:

PyObject *PyUnicode_Decode(const char *s, Py_ssize_t size, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the encoded string *s*. *encoding* and *errors* have the same meaning as the parameters of the same name in the **str()** built-in function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsEncodedString(PyObject *unicode, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object and return the result as Python bytes object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode **encode()** method. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

UTF-8 Codecs

These are the UTF-8 codec APIs:

PyObject *PyUnicode_DecodeUTF8(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF8Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **PyUnicode_DecodeUTF8()**. If *consumed* is not `NULL`, trailing incomplete UTF-8 byte sequences will not be treated

as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF8String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is "strict". Return `NULL` if an exception was raised by the codec.

const char *PyUnicode_AsUTF8AndSize(PyObject *unicode, Py_ssize_t *size)

Part of the Stable ABI since version 3.10.
Return a pointer to the UTF-8 encoding of the Unicode object, and store the size of the encoded representation (in bytes) in *size*. The *size* argument can be `NULL`; in this case no size will be stored. The returned buffer always has an extra null byte appended (not included in *size*), regardless of whether there are any other null code points.

In the case of an error, `NULL` is returned with an exception set and no *size* is stored.

This caches the UTF-8 representation of the string in the Unicode object, and subsequent calls will return a pointer to the same buffer. The caller is not responsible for deallocating the buffer. The buffer is deallocated and pointers to it become invalid when the Unicode object is garbage collected.

New in version 3.3.

Changed in version 3.7: The return type is now `const char *` rather of `char *`.

Changed in version 3.10: This function is a part of the limited API.

const char *PyUnicode_AsUTF8(PyObject *unicode)

As **`PyUnicode_AsUTF8AndSize()`**, but does not store the size.

New in version 3.3.

Changed in version 3.7: The return type is now `const char *` rather of `char *`.

UTF-32 Codecs

These are the UTF-32 codec APIs:

PyObject *PyUnicode_DecodeUTF32(const char *s, Py_ssize_t size, const char *errors, int *byteorder)

Return value: New reference. Part of the Stable ABI.
Decode *size* bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to "strict".

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If `*byteorder` is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output.

After completion, **byteorder* is set to the current byte order at the end of input data.

If *byteorder* is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF32Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF32()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeUTF32Stateful()`** will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF32String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is "strict". Return `NULL` if an exception was raised by the codec.

UTF-16 Codecs

These are the UTF-16 codec APIs:

PyObject *PyUnicode_DecodeUTF16(const char *s, Py_ssize_t size, const char *errors, int *byteorder)

Return value: New reference. Part of the Stable ABI.
Decode *size* bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to "strict".

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If `*byteorder` is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output (where it will result in either a

`\ufeff` or a `\ufffe` character).

After completion, `*byteorder` is set to the current byte order at the end of input data.

If *byteorder* is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF16Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF16()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeUTF16Stateful()`** will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF16String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-7 Codecs

These are the UTF-7 codec APIs:

PyObject *PyUnicode_DecodeUTF7(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the UTF-7 encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF7Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF7()`**. If *consumed* is not `NULL`, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

Unicode-Escape Codecs

These are the "Unicode Escape" codec APIs:

PyObject *PyUnicode_DecodeUnicodeEscape(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsUnicodeEscapeString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using Unicode-Escape and return the result as a bytes object. Error handling is "strict". Return `NULL` if an exception was raised by the codec.

Raw-Unicode-Escape Codecs

These are the "Raw Unicode Escape" codec APIs:

PyObject *PyUnicode_DecodeRawUnicodeEscape(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsRawUnicodeEscapeString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using Raw-Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Latin-1 Codecs

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

PyObject *PyUnicode_DecodeLatin1(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Latin-1 encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsLatin1String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using Latin-1 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

ASCII Codecs

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject *PyUnicode_DecodeASCII(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the ASCII encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsASCIIString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Character Map Codecs

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the **`encodings`** package). The codec uses mappings to encode and decode characters. The mapping objects provided must support the **`__getitem__()`** mapping interface; dictionaries and sequences work well.

These are the mapping codec APIs:

PyObject *PyUnicode_DecodeCharmap(const char *data, Py_ssize_t size, PyObject *mapping, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the encoded string *s* using the given *mapping* object. Return `NULL` if an exception was raised by the codec.

If *mapping* is `NULL`, Latin-1 decoding will be applied. Else *mapping* must map bytes ordinals (integers in the range from 0 to 255) to Unicode strings, integers (which are then interpreted as Unicode ordinals) or `None`. Unmapped data bytes – ones which cause a **`LookupError`**, as well as ones which get mapped to `None`, `0xFFFE` or `'\ufffe'`, are treated as undefined mappings and cause an error.

PyObject *PyUnicode_AsCharmapString(PyObject *unicode, PyObject *mapping)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using the given *mapping* object and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

The *mapping* object must map Unicode ordinal integers to bytes objects, integers in the range from 0 to 255 or `None`. Unmapped character ordinals (ones which cause a **`LookupError`**) as well as mapped to `None` are treated as "undefined mapping" and cause an error.

The following codec API is special in that maps Unicode to Unicode.

PyObject *PyUnicode_Translate(PyObject *str, PyObject *table, const char *errors)

Return value: New reference. Part of the Stable ABI.
Translate a string by applying a character mapping table to it and return the resulting Unicode object. Return `NULL` if an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or `None` (causing deletion of the character).

Mapping tables need only provide the **`__getitem__()`** interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a **`LookupError`**) are left untouched and are copied as-is.

errors has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

MBCS codecs for Windows

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

PyObject *PyUnicode_DecodeMBCS(const char *s, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.

Create a Unicode object by decoding *size* bytes of the MBCS encoded string *s*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeMBCSStateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeMBCS()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeMBCSStateful()`** will not decode trailing lead byte and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsMBCSString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.
Encode a Unicode object using MBCS and return the result as Python bytes object. Error handling is "strict". Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_EncodeCodePage(int code_page, PyObject *unicode, const char *errors)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.
Encode the Unicode object using the specified code page and return a Python bytes object. Return `NULL` if an exception was raised by the codec. Use **`CP_ACP`** code page to get the MBCS encoder.

New in version 3.3.

Methods & Slots

Methods and Slot Functions

The following APIs are capable of handling Unicode objects and

strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

PyObject *PyUnicode_Concat(PyObject *left, PyObject *right)

Return value: New reference. Part of the Stable ABI.
Concat two strings giving a new Unicode string.

PyObject *PyUnicode_Split(PyObject *s, PyObject *sep, Py_ssize_t maxsplit)

Return value: New reference. Part of the Stable ABI.
Split a string giving a list of Unicode strings. If *sep* is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most *maxsplit* splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

PyObject *PyUnicode_Splitlines(PyObject *s, int keepend)

Return value: New reference. Part of the Stable ABI.
Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If *keepend* is `0`, the line break characters are not included in the resulting strings.

PyObject *PyUnicode_Join(PyObject *separator, PyObject *seq)

Return value: New reference. Part of the Stable ABI.
Join a sequence of strings using the given *separator* and return the resulting Unicode string.

Py_ssize_t PyUnicode_Tailmatch(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI.
Return `1` if *substr* matches `str[start:end]` at the given tail end (*direction* == `-1` means to do a prefix match, *direction* == `1` a suffix match), `0` otherwise. Return `-1` if an error occurred.

Py_ssize_t PyUnicode_Find(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI.
Return the first position of *substr* in `str[start:end]` using the given *direction* (*direction* == `1` means to do a forward search, *direction* == `-1` a backward search). The return value is the index of the first match; a value of `-1` indicates that no match was found, and `-2` indicates that an error occurred and an exception has been set.

Py_ssize_t PyUnicode_FindChar(PyObject *str, Py_UCS4 ch, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI since version 3.7.
Return the first position of the character *ch* in `str[start:end]` using the given *direction* (*direction* == `1` means to do a forward search, *direction* == `-1` a backward search). The return value is the index of the first match; a value of `-1` indicates that no match was found, and `-2` indicates that an error occurred and an exception has been set.

New in version 3.3.

Changed in version 3.7: start and *end* are now adjusted to behave like `str[start:end]`.

Py_ssize_t PyUnicode_Count(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end)

Part of the Stable ABI.
Return the number of non-overlapping occurrences of *substr* in `str[start:end]`. Return `-1` if an error occurred.

PyObject *PyUnicode_Replace(PyObject *str, PyObject *substr, PyObject *replstr, Py_ssize_t maxcount)

Return value: New reference. Part of the Stable ABI.
Replace at most *maxcount* occurrences of *substr* in *str* with *replstr* and return the resulting Unicode object. *maxcount* ==

`-1` means replace all occurrences.

int PyUnicode_Compare(PyObject *left, PyObject *right)

Part of the Stable ABI.
Compare two strings and return `-1`, `0`, `1` for less than, equal, and greater than, respectively.

This function returns `-1` upon failure, so one should call **`PyErr_Occurred()`** to check for errors.

int PyUnicode_CompareWithASCIIString(PyObject *uni, const char *string)

Part of the Stable ABI.
Compare a Unicode object, *uni*, with *string* and return `-1`, `0`, `1` for less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters.

This function does not raise exceptions.

PyObject *PyUnicode_RichCompare(PyObject *left, PyObject *right, int op)

Return value: New reference. Part of the Stable ABI.
Rich compare two Unicode strings and return one of the following:

- `NULL` in case an exception was raised
- **`Py_True`** or **`Py_False`** for successful comparisons
- **`Py_NotImplemented`** in case the type combination is unknown

Possible values for *op* are **`Py_GT`**, **`Py_GE`**, **`Py_EQ`**, **`Py_NE`**, **`Py_LT`**, and **`Py_LE`**.

PyObject *PyUnicode_Format(PyObject *format, PyObject *args)

Return value: New reference. Part of the Stable ABI.
Return a new string object from *format* and *args*; this is

analogous to `format % args`.

int PyUnicode_Contains(PyObject *container, PyObject *element)

Part of the Stable ABI.
Check whether *element* is contained in *container* and return true or false accordingly.

element has to coerce to a one element Unicode string. `-1` is returned if there was an error.

void PyUnicode_InternInPlace(PyObject **string)

Part of the Stable ABI.
Intern the argument **string* in place. The argument must be the address of a pointer variable pointing to a Python Unicode string object. If there is an existing interned string that is the same as **string*, it sets **string* to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves **string* alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject *PyUnicode_InternFromString(const char *v)

Return value: New reference. Part of the Stable ABI.
A combination of **`PyUnicode_FromString()`** and **`PyUnicode_InternInPlace()`**, returning either a new Unicode string object that has been interned, or a new ("owned") reference to an earlier interned string object with the same value.

Tuple Objects

type PyTupleObject

This subtype of **`PyObject`** represents a Python tuple object.

PyTypeObject PyTuple_Type

Part of the Stable ABI.
This instance of **`PyTypeObject`** represents the Python tuple type; it is the same object as **`tuple`** in the Python layer.

int PyTuple_Check(PyObject *p)

Return true if *p* is a tuple object or an instance of a subtype of the tuple type. This function always succeeds.

int PyTuple_CheckExact(PyObject *p)

Return true if *p* is a tuple object, but not an instance of a subtype of the tuple type. This function always succeeds.

PyObject *PyTuple_New(Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.
Return a new tuple object of size *len*, or `NULL` on failure.

PyObject *PyTuple_Pack(Py_ssize_t n, ...)

Return value: New reference. Part of the Stable ABI.
Return a new tuple object of size *n*, or `NULL` on failure. The tuple values are initialized to the subsequent *n* C arguments pointing to Python objects. `PyTuple_Pack(2, a, b)` is equivalent to `Py_BuildValue("(OO)", a, b)`.

Py_ssize_t PyTuple_Size(PyObject *p)

Part of the Stable ABI.
Take a pointer to a tuple object, and return the size of that

tuple.

Py_ssize_t PyTuple_GET_SIZE(PyObject *p)

Return the size of the tuple *p*, which must be non-`NULL` and point to a tuple; no error checking is performed.

PyObject *PyTuple_GetItem(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is negative or out of bounds, return `NULL` and set an **`IndexError`** exception.

PyObject *PyTuple_GET_ITEM(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference.
Like **`PyTuple_GetItem()`**, but does no checking of its arguments.

PyObject *PyTuple_GetSlice(PyObject *p, Py_ssize_t low, Py_ssize_t high)

Return value: New reference. Part of the Stable ABI.
Return the slice of the tuple pointed to by *p* between *low* and *high*, or `NULL` on failure. This is the equivalent of the Python expression `p[low:high]`. Indexing from the end of the list is not supported.

int PyTuple_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)

Part of the Stable ABI.
Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*. Return `0` on success. If *pos* is out of bounds, return `-1` and set an **`IndexError`** exception.

Note

This function “steals” a reference to *o* and discards a reference to an item already in the tuple at the affected position.

void PyTuple_SET_ITEM(PyObject *p, Py_ssize_t pos, PyObject *o)

Like **PyTuple_SetItem()**, but does no error checking, and should *only* be used to fill in brand new tuples.

Note

This function "steals" a reference to *o*, and, unlike **PyTuple_SetItem()**, does *not* discard a reference to any item that is being replaced; any reference in the tuple at position *pos* will be leaked.

int _PyTuple_Resize(PyObject **p, Py_ssize_t newsize)

Can be used to resize a tuple. *newsize* will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns `0` on success. Client code should never assume that the resulting value of `*p` will be the same as before calling this function. If the object referenced by `*p` is replaced, the original `*p` is destroyed. On failure, returns `-1` and sets `*p` to `NULL`, and raises **MemoryError** or **SystemError**.

Struct Sequence Objects

Struct sequence objects are the C equivalent of **namedtuple()** objects, i.e. a sequence whose items can also be accessed through attributes. To create a struct sequence, you first have to create a specific struct sequence type.

PyTypeObject *PyStructSequence_NewType(PyStructSequence_Desc *desc)

Return value: New reference. Part of the Stable ABI.
Create a new struct sequence type from the data in *desc*, described below. Instances of the resulting type can be created with **PyStructSequence_New()**.

void PyStructSequence_InitType(PyTypeObject *type, PyStructSequence_Desc *desc)

Initializes a struct sequence type *type* from *desc* in place.

int PyStructSequence_InitType2(PyTypeObject *type, PyStructSequence_Desc *desc)

The same as `PyStructSequence_InitType`, but returns `0` on success and `-1` on failure.

New in version 3.4.

type PyStructSequence_Desc

Part of the Stable ABI (including all members).
Contains the meta information of a struct sequence type to create.

Member	Meaning
name	name of the struct sequence type
doc	pointer to docstring for the type or `NULL` to omit
fields	pointer to `NULL`-terminated array with field names of the new type
n_in_sequence	number of fields visible to the Python side (if used as tuple)

type PyStructSequence_Field

Part of the Stable ABI (including all members).
Describes a field of a struct sequence. As a struct sequence is modeled as a tuple, all fields are typed as PyObject*. The index in the **fields** array of the **PyStructSequence_Desc** determines which field of the struct sequence is described.

Member	Meaning
name	name for the field or `NULL` to end the list of named fields, set to `PyStructSequence_UnnamedField` to leave unnamed
doc	field docstring or `NULL` to omit

name	char * field or `NULL` to end the list of named fields, set to `PyStructSequence_UnnamedField` to leave unnamed
doc	char * field docstring or `NULL` to omit

const char *const PyStructSequence_UnnamedField

Part of the Stable ABI since version 3.11.
Special value for a field name to leave it unnamed.

Changed in version 3.9: The type was changed from `char *`.

PyObject *PyStructSequence_New(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI.
Creates an instance of *type*, which must have been created with `PyStructSequence_NewType()`.

PyObject *PyStructSequence_GetItem(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object at position *pos* in the struct sequence pointed to by *p*. No bounds checking is performed.

PyObject *PyStructSequence_GET_ITEM(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference.
Macro equivalent of `PyStructSequence_GetItem()`.

void PyStructSequence_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)

Part of the Stable ABI.
Sets the field at index *pos* of the struct sequence *p* to value *o*. Like `PyTuple_SET_ITEM()`, this should only be used to fill in brand new instances.

Note

This function “steals” a reference to *o*.

void PyStructSequence_SET_ITEM(PyObject *p, Py_ssize_t *pos, PyObject *o)

Similar to **`PyStructSequence_SetItem()`**, but implemented as a static inlined function.

Note

This function “steals” a reference to *o*.

List Objects

type PyListObject

This subtype of **PyObject** represents a Python list object.

PyTypeObject PyList_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python list type. This is the same object as **list** in the Python layer.

int PyList_Check(PyObject *p)

Return true if *p* is a list object or an instance of a subtype of the list type. This function always succeeds.

int PyList_CheckExact(PyObject *p)

Return true if *p* is a list object, but not an instance of a subtype of the list type. This function always succeeds.

PyObject *PyList_New(Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.
Return a new list of length *len* on success, or `NULL` on failure.

Note

If *len* is greater than zero, the returned list object's items are set to `NULL`. Thus you cannot use abstract API functions such as **PySequence_SetItem()** or expose the object to Python code before setting all items to a real object with **PyList_SetItem()**.

Py_ssize_t PyList_Size(PyObject *list)

Part of the Stable ABI.

Return the length of the list object in *list*; this is equivalent to `len(list)` on a list object.

Py_ssize_t PyList_GET_SIZE(PyObject *list)

Similar to **`PyList_Size()`**, but without error checking.

PyObject *PyList_GetItem(PyObject *list, Py_ssize_t index)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object at position *index* in the list pointed to by *list*. The position must be non-negative; indexing from the end of the list is not supported. If *index* is out of bounds (<0 or >=len(list)), return `NULL` and set an **`IndexError`** exception.

PyObject *PyList_GET_ITEM(PyObject *list, Py_ssize_t i)

Return value: Borrowed reference.
Similar to **`PyList_GetItem()`**, but without error checking.

int PyList_SetItem(PyObject *list, Py_ssize_t index, PyObject *item)

Part of the Stable ABI.
Set the item at index *index* in list to *item*. Return `0` on success. If *index* is out of bounds, return `-1` and set an **`IndexError`** exception.

Note

This function “steals” a reference to *item* and discards a reference to an item already in the list at the affected position.

void PyList_SET_ITEM(PyObject *list, Py_ssize_t i, PyObject *o)

Macro form of **`PyList_SetItem()`** without error checking. This is normally only used to fill in new lists where there is no previous content.

Note

This macro “steals” a reference to *item*, and, unlike **PyList_SetItem()**, does *not* discard a reference to any item that is being replaced; any reference in *list* at position *i* will be leaked.

int PyList_Insert(PyObject *list, Py_ssize_t index, PyObject *item)

Part of the Stable ABI.
Insert the item *item* into list *list* in front of index *index*. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.insert(index, item)`.

int PyList_Append(PyObject *list, PyObject *item)

Part of the Stable ABI.
Append the object *item* at the end of list *list*. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.append(item)`.

PyObject *PyList_GetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high)

Return value: New reference. Part of the Stable ABI.
Return a list of the objects in *list* containing the objects *between low* and *high*. Return `NULL` and set an exception if unsuccessful. Analogous to `list[low:high]`. Indexing from the end of the list is not supported.

int PyList_SetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)

Part of the Stable ABI.
Set the slice of *list* between *low* and *high* to the contents of *itemlist*. Analogous to `list[low:high] = itemlist`. The *itemlist* may be `NULL`, indicating the assignment of an empty list (slice deletion). Return `0` on success, `-1` on failure. Indexing from the end of the list is not supported.

int PyList_Sort(PyObject *list)

Part of the Stable ABI.
Sort the items of *list* in place. Return `0` on success, `-1` on failure. This is equivalent to `list.sort()`.

int PyList_Reverse(PyObject *list)

Part of the Stable ABI.
Reverse the items of *list* in place. Return `0` on success, `-1` on failure. This is the equivalent of `list.reverse()`.

PyObject *PyList_AsTuple(PyObject *list)

Return value: New reference. Part of the Stable ABI.
Return a new tuple object containing the contents of *list*; equivalent to `tuple(list)`.

Dictionary Objects

type PyDictObject

This subtype of **PyObject** represents a Python dictionary object.

PyTypeObject PyDict_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python dictionary type. This is the same object as **dict** in the Python layer.

int PyDict_Check(PyObject *p)

Return true if *p* is a dict object or an instance of a subtype of the dict type. This function always succeeds.

int PyDict_CheckExact(PyObject *p)

Return true if *p* is a dict object, but not an instance of a subtype of the dict type. This function always succeeds.

PyObject *PyDict_New()

Return value: New reference. Part of the Stable ABI.
Return a new empty dictionary, or `NULL` on failure.

PyObject *PyDictProxy_New(PyObject *mapping)

Return value: New reference. Part of the Stable ABI.
Return a **types.MappingProxyType** object for a mapping which enforces read-only behavior. This is normally used to create a view to prevent modification of the dictionary for non-dynamic class types.

void PyDict_Clear(PyObject *p)

Part of the Stable ABI.
Empty an existing dictionary of all key-value pairs.

int PyDict_Contains(PyObject *p, PyObject *key)

Part of the Stable ABI.
Determine if dictionary *p* contains *key*. If an item in *p* is matches *key*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `key in p`.

PyObject *PyDict_Copy(PyObject *p)

Return value: New reference. Part of the Stable ABI.
Return a new dictionary that contains the same key-value pairs as *p*.

int PyDict_SetItem(PyObject *p, PyObject *key, PyObject *val)

Part of the Stable ABI.
Insert *val* into the dictionary *p* with a key of *key*. *key* must be hashable; if it isn't, **`TypeError`** will be raised. Return `0` on success or `-1` on failure. This function *does not* steal a reference to *val*.

int PyDict_SetItemString(PyObject *p, const char *key, PyObject *val)

Part of the Stable ABI.
Insert *val* into the dictionary *p* using *key* as a key. *key* should be a const char*. The key object is created using `PyUnicode_FromString(key)`. Return `0` on success or `-1` on failure. This function *does not* steal a reference to *val*.

int PyDict_DelItem(PyObject *p, PyObject *key)

Part of the Stable ABI.
Remove the entry in dictionary *p* with key *key*. *key* must be hashable; if it isn't, **`TypeError`** is raised. If *key* is not in the dictionary, **`KeyError`** is raised. Return `0` on success or `-1` on failure.

int PyDict_DelItemString(PyObject *p, const char *key)

Part of the Stable ABI.
Remove the entry in dictionary *p* which has a key specified by the string *key*. If *key* is not in the dictionary, **KeyError** is raised. Return `0` on success or `-1` on failure.

PyObject *PyDict_GetItem(PyObject *p, PyObject *key)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object from dictionary *p* which has a key *key*. Return `NULL` if the key *key* is not present, but *without* setting an exception.

Note that exceptions which occur while calling **__hash__()** and **__eq__()** methods will get suppressed. To get error reporting use **PyDict_GetItemWithError()** instead.

Changed in version 3.10: Calling this API without GIL held had been allowed for historical reason. It is no longer allowed.

PyObject *PyDict_GetItemWithError(PyObject *p, PyObject *key)

Return value: Borrowed reference. Part of the Stable ABI.
Variant of **PyDict_GetItem()** that does not suppress exceptions. Return `NULL` **with** an exception set if an exception occurred. Return `NULL` **without** an exception set if the key wasn't present.

PyObject *PyDict_GetItemString(PyObject *p, const char *key)

Return value: Borrowed reference. Part of the Stable ABI.
This is the same as **PyDict_GetItem()**, but *key* is specified as a const char*, rather than a PyObject*.

Note that exceptions which occur while calling **__hash__()** and **__eq__()** methods and creating a temporary string object will get suppressed. To get error reporting use **PyDict_GetItemWithError()** instead.

PyObject *PyDict_SetDefault(PyObject *p, PyObject *key, PyObject *defaultobj)

Return value: Borrowed reference.

This is the same as the Python-level **dict.setdefault()**. If present, it returns the value corresponding to *key* from the dictionary *p*. If the key is not in the dict, it is inserted with value *defaultobj* and *defaultobj* is returned. This function evaluates the hash function of *key* only once, instead of evaluating it independently for the lookup and the insertion.

New in version 3.4.

PyObject *PyDict_Items(PyObject *p)

Return value: New reference. Part of the Stable ABI.
Return a **PyListObject** containing all the items from the dictionary.

PyObject *PyDict_Keys(PyObject *p)

Return value: New reference. Part of the Stable ABI.
Return a **PyListObject** containing all the keys from the dictionary.

PyObject *PyDict_Values(PyObject *p)

Return value: New reference. Part of the Stable ABI.
Return a **PyListObject** containing all the values from the dictionary *p*.

Py_ssize_t PyDict_Size(PyObject *p)

Part of the Stable ABI.
Return the number of items in the dictionary. This is equivalent to `len(p)` on a dictionary.

int PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)

Part of the Stable ABI.
Iterate over all key-value pairs in the dictionary *p*. The **Py_ssize_t** referred to by *ppos* must be initialized to `0` prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters *pkey* and

pvalue should either point to PyObject* variables that will be filled in with each key and value, respectively, or may be `NULL`. Any references returned through them are borrowed. *ppos* should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value))
    /* do something interesting with the values...
    ...
}
```

The dictionary *p* should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value))
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}
```

int PyDict_Merge(PyObject *a, PyObject *b, int override)

Part of the Stable ABI.
Iterate over mapping object *b* adding key-value pairs to dictionary *a*. *b* may be a dictionary, or any object supporting **`PyMapping_Keys()`** and **`PyObject_GetItem()`**. If *override* is true, existing pairs in *a* will be replaced if a matching key is found in *b*, otherwise pairs will only be added if there is not a matching key in *a*. Return `0` on success or `-1` if an exception was raised.

int PyDict_Update(PyObject *a, PyObject *b)

Part of the Stable ABI.
This is the same as `PyDict_Merge(a, b, 1)` in C, and is similar to `a.update(b)` in Python except that **`PyDict_Update()`** doesn't fall back to the iterating over a sequence of key value pairs if the second argument has no "keys" attribute. Return `0` on success or `-1` if an exception was raised.

int PyDict_MergeFromSeq2(PyObject *a, PyObject *seq2, int override)

Part of the Stable ABI.
Update or merge into dictionary *a*, from the key-value pairs in *seq2*. *seq2* must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if *override* is true, else the first wins. Return `0` on success or `-1` if an exception was raised. Equivalent Python (except for the return value):

```
def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value
```

Set Objects

This section details the public API for **`set`** and **`frozenset`** objects. Any functionality not listed below is best accessed using either the abstract object protocol (including **`PyObject_CallMethod()`**, **`PyObject_RichCompareBool()`**, **`PyObject_Hash()`**, **`PyObject_Repr()`**, **`PyObject_IsTrue()`**, **`PyObject_Print()`**, and **`PyObject_GetIter()`**) or the abstract number protocol (including **`PyNumber_And()`**, **`PyNumber_Subtract()`**, **`PyNumber_Or()`**, **`PyNumber_Xor()`**, **`PyNumber_InPlaceAnd()`**, **`PyNumber_InPlaceSubtract()`**, **`PyNumber_InPlaceOr()`**, and **`PyNumber_InPlaceXor()`**).

type PySetObject

This subtype of **`PyObject`** is used to hold the internal data for both **`set`** and **`frozenset`** objects. It is like a **`PyDictObject`** in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and all are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

PyTypeObject PySet_Type

Part of the Stable ABI.
This is an instance of **`PyTypeObject`** representing the Python **`set`** type.

PyTypeObject PyFrozenSet_Type

Part of the Stable ABI.
This is an instance of **`PyTypeObject`** representing the Python **`frozenset`** type.

The following type check macros work on pointers to any Python

object. Likewise, the constructor functions work with any iterable Python object.

int PySet_Check(PyObject *p)

Return true if *p* is a **set** object or an instance of a subtype. This function always succeeds.

int PyFrozenSet_Check(PyObject *p)

Return true if *p* is a **frozenset** object or an instance of a subtype. This function always succeeds.

int PyAnySet_Check(PyObject *p)

Return true if *p* is a **set** object, a **frozenset** object, or an instance of a subtype. This function always succeeds.

int PySet_CheckExact(PyObject *p)

Return true if *p* is a **set** object but not an instance of a subtype. This function always succeeds.

New in version 3.10.

int PyAnySet_CheckExact(PyObject *p)

Return true if *p* is a **set** object or a **frozenset** object but not an instance of a subtype. This function always succeeds.

int PyFrozenSet_CheckExact(PyObject *p)

Return true if *p* is a **frozenset** object but not an instance of a subtype. This function always succeeds.

PyObject *PySet_New(PyObject *iterable)

Return value: New reference. Part of the Stable ABI.
Return a new **set** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty set. Return the new set on success or `NULL` on failure. Raise **TypeError** if *iterable* is not actually iterable. The constructor is also useful for copying a set (`c=set(s)`).

PyObject *PyFrozenSet_New(PyObject *iterable)

Return value: New reference. Part of the Stable ABI.
Return a new **frozenset** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty frozenset. Return the new set on success or `NULL` on failure. Raise **TypeError** if *iterable* is not actually iterable.

The following functions and macros are available for instances of **set** or **frozenset** or instances of their subtypes.

Py_ssize_t PySet_Size(PyObject *anyset)

Part of the Stable ABI.
Return the length of a **set** or **frozenset** object. Equivalent to `len(anyset)`. Raises a **PyExc_SystemError** if *anyset* is not a **set**, **frozenset**, or an instance of a subtype.

Py_ssize_t PySet_GET_SIZE(PyObject *anyset)

Macro form of **PySet_Size()** without error checking.

int PySet_Contains(PyObject *anyset, PyObject *key)

Part of the Stable ABI.
Return `1` if found, `0` if not found, and `-1` if an error is encountered. Unlike the Python **__contains__()** method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a **TypeError** if the *key* is unhashable. Raise **PyExc_SystemError** if *anyset* is not a **set**, **frozenset**, or an instance of a subtype.

int PySet_Add(PyObject *set, PyObject *key)

Part of the Stable ABI.
Add *key* to a **set** instance. Also works with **frozenset** instances (like **PyTuple_SetItem()** it can be used to fill in the values of brand new frozensets before they are exposed to other code). Return `0` on success or `-1` on failure. Raise a **TypeError** if the *key* is unhashable. Raise a **MemoryError** if there is no room to grow. Raise a **SystemError** if *set* is

not an instance of **set** or its subtype.

The following functions are available for instances of **set** or its subtypes but not for instances of **frozenset** or its subtypes.

int PySet_Discard(PyObject *set, PyObject *key)

Part of the Stable ABI.
Return `1` if found and removed, `0` if not found (no action taken), and `-1` if an error is encountered. Does not raise **KeyError** for missing keys. Raise a **TypeError** if the *key* is unhashable. Unlike the Python **discard()** method, this function does not automatically convert unhashable sets into temporary frozensets. Raise **PyExc_SystemError** if *set* is not an instance of **set** or its subtype.

PyObject *PySet_Pop(PyObject *set)

Return value: New reference. Part of the Stable ABI.
Return a new reference to an arbitrary object in the *set*, and removes the object from the *set*. Return `NULL` on failure. Raise **KeyError** if the set is empty. Raise a **SystemError** if *set* is not an instance of **set** or its subtype.

int PySet_Clear(PyObject *set)

Part of the Stable ABI.
Empty an existing set of all elements.

Function Objects

There are a few functions specific to Python functions.

type PyFunctionObject

The C structure used for functions.

PyTypeObject PyFunction_Type

This is an instance of **`PyTypeObject`** and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

int PyFunction_Check(PyObject *o)

Return true if *o* is a function object (has type **`PyFunction_Type`**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyFunction_New(PyObject *code, PyObject *globals)

Return value: New reference.
Return a new function object associated with the code object *code*. *globals* must be a dictionary with the global variables accessible to the function.

The function's docstring and name are retrieved from the code object. *__module__* is retrieved from *globals*. The argument defaults, annotations and closure are set to `NULL`. *__qualname__* is set to the same value as the code object's `co_qualname` field.

PyObject *PyFunction_NewWithQualName(PyObject *code, PyObject *globals, PyObject *qualname)

Return value: New reference.
As **`PyFunction_New()`**, but also allows setting the function object's `__qualname__` attribute. *qualname* should be a

unicode object or `NULL`; if `NULL`, the `__qualname__` attribute is set to the same value as the code object's `co_qualname` field.

New in version 3.3.

PyObject *PyFunction_GetCode(PyObject *op)

Return value: Borrowed reference.
Return the code object associated with the function object *op*.

PyObject *PyFunction_GetGlobals(PyObject *op)

Return value: Borrowed reference.
Return the globals dictionary associated with the function object *op*.

PyObject *PyFunction_GetModule(PyObject *op)

Return value: Borrowed reference.
Return a borrowed reference to the *__module__* attribute of the function object *op*. It can be *NULL*.

This is normally a string containing the module name, but can be set to any other object by Python code.

PyObject *PyFunction_GetDefaults(PyObject *op)

Return value: Borrowed reference.
Return the argument default values of the function object *op*. This can be a tuple of arguments or `NULL`.

int PyFunction_SetDefaults(PyObject *op, PyObject *defaults)

Set the argument default values for the function object *op*. *defaults* must be `Py_None` or a tuple.

Raises **`SystemError`** and returns `-1` on failure.

PyObject *PyFunction_GetClosure(PyObject *op)

Return value: Borrowed reference.
Return the closure associated with the function object *op*.

This can be `NULL` or a tuple of cell objects.

int PyFunction_SetClosure(PyObject *op, PyObject *closure)

Set the closure associated with the function object *op*. *closure* must be `Py_None` or a tuple of cell objects.

Raises **`SystemError`** and returns `-1` on failure.

PyObject *PyFunction_GetAnnotations(PyObject *op)

Return value: Borrowed reference.
Return the annotations of the function object *op*. This can be a mutable dictionary or `NULL`.

int PyFunction_SetAnnotations(PyObject *op, PyObject *annotations)

Set the annotations for the function object *op*. *annotations* must be a dictionary or `Py_None`.

Raises **`SystemError`** and returns `-1` on failure.

Instance Method Objects

An instance method is a wrapper for a **`PyCFunction`** and the new way to bind a **`PyCFunction`** to a class object. It replaces the former call `PyMethod_New(func, NULL, class)`.

PyTypeObject PyInstanceMethod_Type

This instance of **`PyTypeObject`** represents the Python instance method type. It is not exposed to Python programs.

int PyInstanceMethod_Check(PyObject *o)

Return true if *o* is an instance method object (has type **`PyInstanceMethod_Type`**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyInstanceMethod_New(PyObject *func)

Return value: New reference.
Return a new instance method object, with *func* being any callable object. *func* is the function that will be called when the instance method is called.

PyObject *PyInstanceMethod_Function(PyObject *im)

Return value: Borrowed reference.
Return the function object associated with the instance method *im*.

PyObject *PyInstanceMethod_GET_FUNCTION(PyObject *im)

Return value: Borrowed reference.
Macro version of **`PyInstanceMethod_Function()`** which avoids error checking.

Method Objects

Methods are bound function objects. Methods are always bound to an instance of a user-defined class. Unbound methods (methods bound to a class object) are no longer available.

PyTypeObject PyMethod_Type

This instance of **PyTypeObject** represents the Python method type. This is exposed to Python programs as `types.MethodType`.

int PyMethod_Check(PyObject *o)

Return true if *o* is a method object (has type **PyMethod_Type**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyMethod_New(PyObject *func, PyObject *self)

Return value: New reference.
Return a new method object, with *func* being any callable object and *self* the instance the method should be bound. *func* is the function that will be called when the method is called. *self* must not be `NULL`.

PyObject *PyMethod_Function(PyObject *meth)

Return value: Borrowed reference.
Return the function object associated with the method *meth*.

PyObject *PyMethod_GET_FUNCTION(PyObject *meth)

Return value: Borrowed reference.
Macro version of **PyMethod_Function()** which avoids error checking.

PyObject *PyMethod_Self(PyObject *meth)

Return value: Borrowed reference.
Return the instance associated with the method *meth*.

PyObject *PyMethod_GET_SELF(PyObject *meth)

Return value: Borrowed reference.
Macro version of `PyMethod_Self()` which avoids error checking.

Cell Objects

"Cell" objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

type PyCellObject

The C structure used for cell objects.

PyTypeObject PyCell_Type

The type object corresponding to cell objects.

int PyCell_Check(ob)

Return true if *ob* is a cell object; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyCell_New(PyObject *ob)

Return value: New reference.
Create and return a new cell object containing the value *ob*. The parameter may be `NULL`.

PyObject *PyCell_Get(PyObject *cell)

Return value: New reference.
Return the contents of the cell *cell*.

PyObject *PyCell_GET(PyObject *cell)

Return value: Borrowed reference.

Return the contents of the cell *cell*, but without checking that *cell* is non-`NULL` and a cell object.

int PyCell_Set(PyObject *cell, PyObject *value)

Set the contents of the cell object *cell* to *value*. This releases the reference to any current content of the cell. *value* may be `NULL`. *cell* must be non-`NULL`; if it is not a cell object, `-1` will be returned. On success, `0` will be returned.

void PyCell_SET(PyObject *cell, PyObject *value)

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-`NULL` and must be a cell object.

Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn't yet been bound into a function.

type PyCodeObject

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

PyTypeObject PyCode_Type

This is an instance of **`PyTypeObject`** representing the Python **`code`** type.

int PyCode_Check(PyObject *co)

Return true if *co* is a **`code`** object. This function always succeeds.

int PyCode_GetNumFree(PyCodeObject *co)

Return the number of free variables in *co*.

PyCodeObject *PyCode_New(int argcount, int kwonlyargcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, int firstlineno, PyObject *linetable, PyObject *exceptiontable)

Return value: New reference.
Return a new code object. If you need a dummy code object to create a frame, use **`PyCode_NewEmpty()`** instead. Calling **`PyCode_New()`** directly will bind you to a precise Python version since the definition of the bytecode changes often. The many arguments of this function are inter-dependent in complex ways, meaning that subtle changes to values are likely to result in incorrect execution or VM crashes. Use this

function only with extreme care.

Changed in version 3.11: Added `exceptiontable` parameter.

PyCodeObject *PyCode_NewWithPosOnlyArgs(int argcount, int posonlyargcount, int kwonlyargcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, int firstlineno, PyObject *linetable, PyObject *exceptiontable)

Return value: New reference.
Similar to **`PyCode_New()`**, but with an extra "posonlyargcount" for positional-only arguments. The same caveats that apply to `PyCode_New` also apply to this function.

New in version 3.8.

Changed in version 3.11: Added `exceptiontable` parameter.

PyCodeObject *PyCode_NewEmpty(const char *filename, const char *funcname, int firstlineno)

Return value: New reference.
Return a new empty code object with the specified filename, function name, and first line number. The resulting code object will raise an `Exception` if executed.

int PyCode_Addr2Line(PyCodeObject *co, int byte_offset)

Return the line number of the instruction that occurs on or before `byte_offset` and ends after it. If you just need the line number of a frame, use **`PyFrame_GetLineNumber()`** instead.

For efficiently iterating over the line numbers in a code object, use the API described in PEP 626 [https://peps.python.org/pep-0626/#out-of-process-debuggers-and-profilers].

int PyCode_Addr2Location(PyObject *co, int byte_offset, int *start_line, int *start_column, int *end_line, int *end_column)

Sets the passed `int` pointers to the source code line and column numbers for the instruction at `byte_offset`. Sets the value to `0` when information is not available for any particular element.

Returns `1` if the function succeeds and 0 otherwise.

PyObject *PyCode_GetCode(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_code')`. Returns a strong reference to a **`PyBytesObject`** representing the bytecode in a code object. On error, `NULL` is returned and an exception is raised.

This `PyBytesObject` may be created on-demand by the interpreter and does not necessarily represent the bytecode actually executed by CPython. The primary use case for this function is debuggers and profilers.

New in version 3.11.

PyObject *PyCode_GetVarnames(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_varnames')`. Returns a new reference to a **`PyTupleObject`** containing the names of the local variables. On error, `NULL` is returned and an exception is raised.

New in version 3.11.

PyObject *PyCode_GetCellvars(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_cellvars')`. Returns a new reference to a **`PyTupleObject`** containing the names of the local variables that are referenced by nested functions. On error, `NULL` is returned and an exception is raised.

New in version 3.11.

PyObject *PyCode_GetFreevars(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_freevars')`. Returns a new reference to a **PyTupleObject** containing the names of the free variables. On error, `NULL` is returned and an exception is raised.

New in version 3.11.

File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (FILE*) support from the C standard library. In Python 3, files and streams use the new `io` module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the `io` APIs instead.

PyObject *PyFile_FromFd(int fd, const char *name, const char *mode, int buffering, const char *encoding, const char *errors, const char *newline, int closefd)

Return value: New reference. Part of the Stable ABI.
Create a Python file object from the file descriptor of an already opened file *fd*. The arguments *name*, *encoding*, *errors* and *newline* can be `NULL` to use the defaults; *buffering* can be *-1* to use the default. *name* is ignored and kept for backward compatibility. Return `NULL` on failure. For a more comprehensive description of the arguments, please refer to the `io.open()` function documentation.

Warning

Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

Changed in version 3.2: Ignore *name* attribute.

int PyObject_AsFileDescriptor(PyObject *p)

Part of the Stable ABI.
Return the file descriptor associated with *p* as an int. If the object is an integer, its value is returned. If not, the object's

fileno() method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns `-1` on failure.

PyObject *PyFile_GetLine(PyObject *p, int n)

Return value: New reference. Part of the Stable ABI.
Equivalent to `p.readline([n])`, this function reads one line from the object *p*. *p* may be a file object or any object with a **readline()** method. If *n* is `0`, exactly one line is read, regardless of the length of the line. If *n* is greater than `0`, no more than *n* bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If *n* is less than `0`, however, one line is read regardless of length, but **EOFError** is raised if the end of the file is reached immediately.

int PyFile_SetOpenCodeHook(Py_OpenCodeHookFunction handler)

Overrides the normal behavior of **io.open_code()** to pass its parameter through the provided handler.

The handler is a function of type PyObject *(*)(PyObject *path, void *userData), where *path* is guaranteed to be **PyUnicodeObject**.

The *userData* pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

As this hook is intentionally used during import, avoid importing new modules during its execution unless they are known to be frozen or available in `sys.modules`.

Once a hook has been set, it cannot be removed or replaced, and later calls to **PyFile_SetOpenCodeHook()** will fail. On failure, the function returns -1 and sets an exception if the interpreter has been initialized.

This function is safe to call before **Py_Initialize()**.

Raises an auditing event `setopencodehook` with no arguments.

New in version 3.8.

int PyFile_WriteObject(PyObject *obj, PyObject *p, int flags)

Part of the Stable ABI.
Write object *obj* to file object *p*. The only supported flag for *flags* is **`Py_PRINT_RAW`**; if given, the **`str()`** of the object is written instead of the **`repr()`**. Return `0` on success or `-1` on failure; the appropriate exception will be set.

int PyFile_WriteString(const char *s, PyObject *p)

Part of the Stable ABI.
Write string *s* to file object *p*. Return `0` on success or `-1` on failure; the appropriate exception will be set.

Module Objects

PyTypeObject PyModule_Type

Part of the Stable ABI.
This instance of **PyTypeObject** represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

int PyModule_Check(PyObject *p)

Return true if *p* is a module object, or a subtype of a module object. This function always succeeds.

int PyModule_CheckExact(PyObject *p)

Return true if *p* is a module object, but not a subtype of **PyModule_Type**. This function always succeeds.

PyObject *PyModule_NewObject(PyObject *name)

Return value: New reference. Part of the Stable ABI since version 3.7.
Return a new module object with the **__name__** attribute set to *name*. The module's **__name__**, **__doc__**, **__package__**, and **__loader__** attributes are filled in (all but **__name__** are set to `None`); the caller is responsible for providing a **__file__** attribute.

New in version 3.3.

Changed in version 3.4: **__package__** and **__loader__** are set to `None`.

PyObject *PyModule_New(const char *name)

Return value: New reference. Part of the Stable ABI.
Similar to **PyModule_NewObject()**, but the name is a UTF-8 encoded string instead of a Unicode object.

PyObject *PyModule_GetDict(PyObject *module)

Return value: Borrowed reference. Part of the Stable ABI.
Return the dictionary object that implements *module*'s namespace; this object is the same as the **__dict__** attribute of the module object. If *module* is not a module object (or a subtype of a module object), **SystemError** is raised and `NULL` is returned.

It is recommended extensions use other `PyModule_*` and `PyObject_*` functions rather than directly manipulate a module's **__dict__**.

PyObject *PyModule_GetNameObject(PyObject *module)

Return value: New reference. Part of the Stable ABI since version 3.7.
Return *module*'s **__name__** value. If the module does not provide one, or if it is not a string, **SystemError** is raised and `NULL` is returned.

New in version 3.3.

const char *PyModule_GetName(PyObject *module)

Part of the Stable ABI.
Similar to **PyModule_GetNameObject()** but return the name encoded to `'utf-8'`.

void *PyModule_GetState(PyObject *module)

Part of the Stable ABI.
Return the "state" of the module, that is, a pointer to the block of memory allocated at module creation time, or `NULL`. See **PyModuleDef.m_size**.

PyModuleDef *PyModule_GetDef(PyObject *module)

Part of the Stable ABI.
Return a pointer to the **PyModuleDef** struct from which the module was created, or `NULL` if the module wasn't created from a definition.

PyObject *PyModule_GetFilenameObject(PyObject *module)

Return value: New reference. Part of the Stable ABI.
Return the name of the file from which *module* was loaded using *module*'s **__file__** attribute. If this is not defined, or if it is not a unicode string, raise **SystemError** and return NULL; otherwise return a reference to a Unicode object.

New in version 3.2.

const char *PyModule_GetFilename(PyObject *module)

Part of the Stable ABI.
Similar to **PyModule_GetFilenameObject()** but return the filename encoded to 'utf-8'.

Deprecated since version 3.2: **PyModule_GetFilename()** raises **UnicodeEncodeError** on unencodable filenames, use **PyModule_GetFilenameObject()** instead.

Initializing C modules

Modules objects are usually created from extension modules (shared libraries which export an initialization function), or compiled-in modules (where the initialization function is added using **PyImport_AppendInittab()**). See Building C and C++ Extensions or Extending Embedded Python for details.

The initialization function can either pass a module definition instance to **PyModule_Create()**, and return the resulting module object, or request "multi-phase initialization" by returning the definition struct itself.

type PyModuleDef

Part of the Stable ABI (including all members).
The module definition struct, which holds all information needed to create a module object. There is usually only one statically initialized variable of this type for each module.

PyModuleDef_Base m_base

Always initialize this member to

PyModuleDef_HEAD_INIT.

const char *m_name
: Name for the new module.

const char *m_doc
: Docstring for the module; usually a docstring variable created with **PyDoc_STRVAR** is used.

Py_ssize_t m_size
: Module state may be kept in a per-module memory area that can be retrieved with **PyModule_GetState()**, rather than in static globals. This makes modules safe for use in multiple sub-interpreters.

  This memory area is allocated based on *m_size* on module creation, and freed when the module object is deallocated, after the **m_free** function has been called, if present.

  Setting `m_size` to `-1` means that the module does not support sub-interpreters, because it has global state.

  Setting it to a non-negative value means that the module can be re-initialized and specifies the additional amount of memory it requires for its state. Non-negative `m_size` is required for multi-phase initialization.

  See **PEP 3121** [https://peps.python.org/pep-3121/] for more details.

PyMethodDef *m_methods
: A pointer to a table of module-level functions, described by **PyMethodDef** values. Can be `NULL` if no functions are present.

PyModuleDef_Slot *m_slots

An array of slot definitions for multi-phase initialization, terminated by a `{0, NULL}` entry. When using single-phase initialization, *m_slots* must be `NULL`.

Changed in version 3.5: Prior to version 3.5, this member was always set to `NULL`, and was defined as:

inquiry m_reload

traverseproc m_traverse

A traversal function to call during GC traversal of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (**`Py_mod_exec`** function). More precisely, this function is not called if **`m_size`** is greater than 0 and the module state (as returned by **`PyModule_GetState()`**) is `NULL`.

Changed in version 3.9: No longer called before the module state is allocated.

inquiry m_clear

A clear function to call during GC clearing of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (**`Py_mod_exec`** function). More precisely, this function is not called if **`m_size`** is greater than 0 and the module state (as returned by **`PyModule_GetState()`**) is `NULL`.

Like **`PyTypeObject.tp_clear`**, this function is not *always* called before a module is deallocated. For example, when reference counting is enough to

determine that an object is no longer used, the cyclic garbage collector is not involved and **`m_free`** is called directly.

Changed in version 3.9: No longer called before the module state is allocated.

freefunc m_free

A function to call during deallocation of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (**`Py_mod_exec`** function). More precisely, this function is not called if **`m_size`** is greater than 0 and the module state (as returned by **`PyModule_GetState()`**) is `NULL`.

Changed in version 3.9: No longer called before the module state is allocated.

Single-phase initialization

The module initialization function may create and return the module object directly. This is referred to as "single-phase initialization", and uses one of the following two module creation functions:

PyObject *PyModule_Create(PyModuleDef *def)

Return value: New reference.
Create a new module object, given the definition in *def*. This behaves like **`PyModule_Create2()`** with *module_api_version* set to **`PYTHON_API_VERSION`**.

PyObject *PyModule_Create2(PyModuleDef *def, int module_api_version)

Return value: New reference. Part of the Stable ABI.
Create a new module object, given the definition in *def*,

assuming the API version *module_api_version*. If that version does not match the version of the running interpreter, a **RuntimeWarning** is emitted.

Note

Most uses of this function should be using **PyModule_Create()** instead; only use this if you are sure you need it.

Before it is returned from in the initialization function, the resulting module object is typically populated using functions like **PyModule_AddObjectRef()**.

Multi-phase initialization

An alternate way to specify extensions is to request "multi-phase initialization". Extension modules created this way behave more like Python modules: the initialization is split between the *creation phase*, when the module object is created, and the *execution phase*, when it is populated. The distinction is similar to the **__new__()** and **__init__()** methods of classes.

Unlike modules created using single-phase initialization, these modules are not singletons: if the *sys.modules* entry is removed and the module is re-imported, a new module object is created, and the old module is subject to normal garbage collection – as with Python modules. By default, multiple modules created from the same definition should be independent: changes to one should not affect the others. This means that all state should be specific to the module object (using e.g. using **PyModule_GetState()**), or its contents (such as the module's **__dict__** or individual classes created with **PyType_FromSpec()**).

All modules created using multi-phase initialization are expected to support sub-interpreters. Making sure multiple modules are independent is typically enough to achieve this.

To request multi-phase initialization, the initialization function

(PyInit_modulename) returns a **`PyModuleDef`** instance with non-empty **`m_slots`**. Before it is returned, the `PyModuleDef` instance must be initialized with the following function:

PyObject *PyModuleDef_Init(PyModuleDef *def)

Return value: Borrowed reference. Part of the Stable ABI since version 3.5.
Ensures a module definition is a properly initialized Python object that correctly reports its type and reference count.

Returns *def* cast to `PyObject*`, or `NULL` if an error occurred.

New in version 3.5.

The *m_slots* member of the module definition must point to an array of `PyModuleDef_Slot` structures:

type PyModuleDef_Slot

int slot

A slot ID, chosen from the available values explained below.

void *value

Value of the slot, whose meaning depends on the slot ID.

New in version 3.5.

The *m_slots* array must be terminated by a slot with id 0.

The available slot types are:

Py_mod_create

Specifies a function that is called to create the module object itself. The *value* pointer of this slot must point to a function of the signature:

PyObject *create_module(PyObject *spec, PyModuleDef *def)

The function receives a **ModuleSpec** instance, as defined in **PEP 451** [https://peps.python.org/pep-0451/], and the module definition. It should return a new module object, or set an error and return `NULL`.

This function should be kept minimal. In particular, it should not call arbitrary Python code, as trying to import the same module again may result in an infinite loop.

Multiple `Py_mod_create` slots may not be specified in one module definition.

If `Py_mod_create` is not specified, the import machinery will create a normal module object using **PyModule_New()**. The name is taken from *spec*, not the definition, to allow extension modules to dynamically adjust to their place in the module hierarchy and be imported under different names through symlinks, all while sharing a single module definition.

There is no requirement for the returned object to be an instance of **PyModule_Type**. Any type can be used, as long as it supports setting and getting import-related attributes. However, only `PyModule_Type` instances may be returned if the `PyModuleDef` has non-`NULL` `m_traverse`, `m_clear`, `m_free`; non-zero `m_size`; or slots other than `Py_mod_create`.

Py_mod_exec

Specifies a function that is called to *execute* the module. This is equivalent to executing the code of a Python module: typically, this function adds classes and constants to the module. The signature of the function is:

int exec_module(PyObject *module)

If multiple `Py_mod_exec` slots are specified, they are processed in the order they appear in the *m_slots* array.

See **PEP 489** [https://peps.python.org/pep-0489/] for more details on multi-phase initialization.

Low-level module creation functions

The following functions are called under the hood when using multi-phase initialization. They can be used directly, for example when creating module objects dynamically. Note that both `PyModule_FromDefAndSpec` and `PyModule_ExecDef` must be called to fully initialize a module.

PyObject *PyModule_FromDefAndSpec(PyModuleDef *def, PyObject *spec)

Return value: New reference.
Create a new module object, given the definition in *module* and the ModuleSpec *spec*. This behaves like **`PyModule_FromDefAndSpec2()`** with *module_api_version* set to **`PYTHON_API_VERSION`**.

New in version 3.5.

PyObject *PyModule_FromDefAndSpec2(PyModuleDef *def, PyObject *spec, int module_api_version)

Return value: New reference. Part of the Stable ABI since version 3.7.
Create a new module object, given the definition in *module* and the ModuleSpec *spec*, assuming the API version *module_api_version*. If that version does not match the version of the running interpreter, a **`RuntimeWarning`** is emitted.

Note

Most uses of this function should be using **`PyModule_FromDefAndSpec()`** instead; only use this if you are sure you need it.

New in version 3.5.

int PyModule_ExecDef(PyObject *module, PyModuleDef *def)

Part of the Stable ABI since version 3.7.
Process any execution slots (**Py_mod_exec**) given in *def*.

New in version 3.5.

int PyModule_SetDocString(PyObject *module, const char *docstring)

Part of the Stable ABI since version 3.7.
Set the docstring for *module* to *docstring*. This function is called automatically when creating a module from `PyModuleDef`, using either `PyModule_Create` or `PyModule_FromDefAndSpec`.

New in version 3.5.

int PyModule_AddFunctions(PyObject *module, PyMethodDef *functions)

Part of the Stable ABI since version 3.7.
Add the functions from the `NULL` terminated *functions* array to *module*. Refer to the **PyMethodDef** documentation for details on individual entries (due to the lack of a shared module namespace, module level "functions" implemented in C typically receive the module as their first parameter, making them similar to instance methods on Python classes). This function is called automatically when creating a module from `PyModuleDef`, using either `PyModule_Create` or `PyModule_FromDefAndSpec`.

New in version 3.5.

Support functions

The module initialization function (if using single phase initialization) or a function called from a module execution slot (if using multi-phase initialization), can use the following functions to help initialize the module state:

int PyModule_AddObjectRef(PyObject *module, const char *name, PyObject *value)

Part of the Stable ABI since version 3.10.
Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function.

On success, return `0`. On error, raise an exception and return `-1`.

Return `NULL` if *value* is `NULL`. It must be called with an exception raised in this case.

Example usage:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (obj == NULL) {
        return -1;
    }
    int res = PyModule_AddObjectRef(module, "spam",
    Py_DECREF(obj);
    return res;
}
```

The example can also be written without checking explicitly if *obj* is `NULL`:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    int res = PyModule_AddObjectRef(module, "spam",
    Py_XDECREF(obj);
    return res;
}
```

Note that `Py_XDECREF()` should be used instead of

`Py_DECREF()` in this case, since *obj* can be `NULL`.

New in version 3.10.

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)

Part of the Stable ABI.
Similar to **`PyModule_AddObjectRef()`**, but steals a reference to *value* on success (if it returns `0`).

The new **`PyModule_AddObjectRef()`** function is recommended, since it is easy to introduce reference leaks by misusing the **`PyModule_AddObject()`** function.

Note

Unlike other functions that steal references, `PyModule_AddObject()` only decrements the reference count of *value* **on success**.

This means that its return value must be checked, and calling code must **`Py_DECREF()`** *value* manually on error.

Example usage:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (obj == NULL) {
        return -1;
    }
    if (PyModule_AddObject(module, "spam", obj) < 0
        Py_DECREF(obj);
        return -1;
    }
    // PyModule_AddObject() stole a reference to ob
    // Py_DECREF(obj) is not needed here
    return 0;
```

```
}
```

The example can also be written without checking explicitly if *obj* is `NULL`:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (PyModule_AddObject(module, "spam", obj) < 0
        Py_XDECREF(obj);
        return -1;
    }
    // PyModule_AddObject() stole a reference to ob
    // Py_DECREF(obj) is not needed here
    return 0;
}
```

Note that `Py_XDECREF()` should be used instead of `Py_DECREF()` in this case, since *obj* can be `NULL`.

int PyModule_AddIntConstant(PyObject *module, const char *name, long value)

Part of the Stable ABI.
Add an integer constant to *module* as *name*. This convenience function can be used from the module's initialization function. Return `-1` on error, `0` on success.

int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)

Part of the Stable ABI.
Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be `NULL`-terminated. Return `-1` on error, `0` on success.

int PyModule_AddIntMacro(PyObject *module, macro)

Add an int constant to *module*. The name and the value are

taken from *macro*. For example `PyModule_AddIntMacro(module, AF_INET)` adds the int constant *AF_INET* with the value of *AF_INET* to *module*. Return `-1` on error, `0` on success.

int PyModule_AddStringMacro(PyObject *module, macro)

Add a string constant to *module*.

int PyModule_AddType(PyObject *module, PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Add a type object to *module*. The type object is finalized by calling internally **`PyType_Ready()`**. The name of the type object is taken from the last component of **`tp_name`** after dot. Return `-1` on error, `0` on success.

New in version 3.9.

Module lookup

Single-phase initialization creates singleton modules that can be looked up in the context of the current interpreter. This allows the module object to be retrieved later with only a reference to the module definition.

These functions will not work on modules created using multi-phase initialization, since multiple such modules can be created from a single definition.

PyObject *PyState_FindModule(PyModuleDef *def)

Return value: Borrowed reference. Part of the Stable ABI.
Returns the module object that was created from *def* for the current interpreter. This method requires that the module object has been attached to the interpreter state with **`PyState_AddModule()`** beforehand. In case the corresponding module object is not found or has not been attached to the interpreter state yet, it returns `NULL`.

int PyState_AddModule(PyObject *module, PyModuleDef *def)

Part of the Stable ABI since version 3.3.
Attaches the module object passed to the function to the interpreter state. This allows the module object to be accessible via **`PyState_FindModule()`**.

Only effective on modules created using single-phase initialization.

Python calls `PyState_AddModule` automatically after importing a module, so it is unnecessary (but harmless) to call it from module initialization code. An explicit call is needed only if the module's own init code subsequently calls `PyState_FindModule`. The function is mainly intended for implementing alternative import mechanisms (either by calling it directly, or by referring to its implementation for details of the required state updates).

The caller must hold the GIL.

Return 0 on success or -1 on failure.

New in version 3.3.

int PyState_RemoveModule(PyModuleDef *def)

Part of the Stable ABI since version 3.3.
Removes the module object created from *def* from the interpreter state. Return 0 on success or -1 on failure.

The caller must hold the GIL.

New in version 3.3.

Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the **`__getitem__()`** method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyTypeObject PySeqIter_Type

Part of the Stable ABI.
Type object for iterator objects returned by **`PySeqIter_New()`** and the one-argument form of the **`iter()`** built-in function for built-in sequence types.

int PySeqIter_Check(op)

Return true if the type of *op* is **`PySeqIter_Type`**. This function always succeeds.

PyObject *PySeqIter_New(PyObject *seq)

Return value: New reference. Part of the Stable ABI.
Return an iterator that works with a general sequence object, *seq*. The iteration ends when the sequence raises **`IndexError`** for the subscripting operation.

PyTypeObject PyCallIter_Type

Part of the Stable ABI.
Type object for iterator objects returned by **`PyCallIter_New()`** and the two-argument form of the **`iter()`** built-in function.

int PyCallIter_Check(op)

Return true if the type of *op* is **`PyCallIter_Type`**. This function always succeeds.

PyObject *PyCallIter_New(PyObject *callable, PyObject *sentinel)

Return value: New reference. Part of the Stable ABI.
Return a new iterator. The first parameter, *callable*, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When *callable* returns a value equal to *sentinel*, the iteration will be terminated.

Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

PyTypeObject PyProperty_Type

Part of the Stable ABI.
The type object for the built-in descriptor types.

PyObject *PyDescr_NewGetSet(PyTypeObject *type, struct PyGetSetDef *getset)

Return value: New reference. Part of the Stable ABI.

PyObject *PyDescr_NewMember(PyTypeObject *type, struct PyMemberDef *meth)

Return value: New reference. Part of the Stable ABI.

PyObject *PyDescr_NewMethod(PyTypeObject *type, struct PyMethodDef *meth)

Return value: New reference. Part of the Stable ABI.

PyObject *PyDescr_NewWrapper(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)

Return value: New reference.

PyObject *PyDescr_NewClassMethod(PyTypeObject *type, PyMethodDef *method)

Return value: New reference. Part of the Stable ABI.

int PyDescr_IsData(PyObject *descr)

Return non-zero if the descriptor objects *descr* describes a

data attribute, or `0` if it describes a method. *descr* must be a descriptor object; there is no error checking.

PyObject *PyWrapper_New(PyObject*, PyObject*)

Return value: New reference. Part of the Stable ABI.

Slice Objects

PyTypeObject PySlice_Type

Part of the Stable ABI.
The type object for slice objects. This is the same as `slice` in the Python layer.

int PySlice_Check(PyObject *ob)

Return true if *ob* is a slice object; *ob* must not be `NULL`. This function always succeeds.

PyObject *PySlice_New(PyObject *start, PyObject *stop, PyObject *step)

Return value: New reference. Part of the Stable ABI.
Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be `NULL`, in which case the `None` will be used for the corresponding attribute. Return `NULL` if the new object could not be allocated.

int PySlice_GetIndices(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Part of the Stable ABI.
Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns `0` on success and `-1` on error with no exception set (unless one of the indices was not `None` and failed to be converted to an integer, in which case `-1` is returned with an exception set).

You probably do not want to use this function.

Changed in version 3.2: The parameter type for the *slice* parameter was `PySliceObject*` before.

int PySlice_GetIndicesEx(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step, Py_ssize_t *slicelength)

Part of the Stable ABI.
Usable replacement for **`PySlice_GetIndices()`**. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns `0` on success and `-1` on error with exception set.

Note

This function is considered not safe for resizable sequences. Its invocation should be replaced by a combination of **`PySlice_Unpack()`** and **`PySlice_AdjustIndices()`** where

```
if (PySlice_GetIndicesEx(slice, length, &start, &s
    // return error
}
```

is replaced by

```
if (PySlice_Unpack(slice, &start, &stop, &step) <
    // return error
}
slicelength = PySlice_AdjustIndices(length, &start
```

Changed in version 3.2: The parameter type for the *slice* parameter was `PySliceObject*` before.

Changed in version 3.6.1: If `Py_LIMITED_API` is not set or set to the value between `0x03050400` and `0x03060000` (not including) or `0x03060100` or higher **`PySlice_GetIndicesEx()`** is implemented as a macro

using **PySlice_Unpack()** and **PySlice_AdjustIndices()**. Arguments *start*, *stop* and *step* are evaluated more than once.

Deprecated since version 3.6.1: If `Py_LIMITED_API` is set to the value less than `0x03050400` or between `0x03060000` and `0x03060100` (not including) **PySlice_GetIndicesEx()** is a deprecated function.

int PySlice_Unpack(PyObject *slice, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Part of the Stable ABI since version 3.7.
Extract the start, stop and step data members from a slice object as C integers. Silently reduce values larger than `PY_SSIZE_T_MAX` to `PY_SSIZE_T_MAX`, silently boost the start and stop values less than `PY_SSIZE_T_MIN` to `PY_SSIZE_T_MIN`, and silently boost the step values less than `-PY_SSIZE_T_MAX` to `-PY_SSIZE_T_MAX`.

Return `-1` on error, `0` on success.

New in version 3.6.1.

Py_ssize_t PySlice_AdjustIndices(Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t step)

Part of the Stable ABI since version 3.7.
Adjust start/end slice indices assuming a sequence of the specified length. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Return the length of the slice. Always successful. Doesn't call Python code.

New in version 3.6.1.

Ellipsis Object

PyObject *Py_Ellipsis

The Python `Ellipsis` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts. Like **`Py_None`** it is a singleton object.

MemoryView objects

A **memoryview** object exposes the C level buffer interface as a Python object which can then be passed around like any other object.

PyObject *PyMemoryView_FromObject(PyObject *obj)

Return value: New reference. Part of the Stable ABI.
Create a memoryview object from an object that provides the buffer interface. If *obj* supports writable buffer exports, the memoryview object will be read/write, otherwise it may be either read-only or read/write at the discretion of the exporter.

PyObject *PyMemoryView_FromMemory(char *mem, Py_ssize_t size, int flags)

Return value: New reference. Part of the Stable ABI since version 3.7.
Create a memoryview object using *mem* as the underlying buffer. *flags* can be one of **PyBUF_READ** or **PyBUF_WRITE**.

New in version 3.3.

PyObject *PyMemoryView_FromBuffer(const Py_buffer *view)

Return value: New reference. Part of the Stable ABI since version 3.11.
Create a memoryview object wrapping the given buffer structure *view*. For simple byte buffers, **PyMemoryView_FromMemory()** is the preferred function.

PyObject *PyMemoryView_GetContiguous(PyObject *obj, int buffertype, char order)

Return value: New reference. Part of the Stable ABI.
Create a memoryview object to a contiguous chunk of

memory (in either ‘C’ or ‘F’ortran *order*) from an object that defines the buffer interface. If memory is contiguous, the memoryview object points to the original memory. Otherwise, a copy is made and the memoryview points to a new bytes object.

int PyMemoryView_Check(PyObject *obj)

Return true if the object *obj* is a memoryview object. It is not currently allowed to create subclasses of **`memoryview`**. This function always succeeds.

Py_buffer *PyMemoryView_GET_BUFFER(PyObject *mview)

Return a pointer to the memoryview’s private copy of the exporter’s buffer. *mview* **must** be a memoryview instance; this macro doesn’t check its type, you must do it yourself or you will risk crashes.

PyObject *PyMemoryView_GET_BASE(PyObject *mview)

Return either a pointer to the exporting object that the memoryview is based on or `NULL` if the memoryview has been created by one of the functions **`PyMemoryView_FromMemory()`** or **`PyMemoryView_FromBuffer()`**. *mview* **must** be a memoryview instance.

Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

int PyWeakref_Check(ob)

Return true if *ob* is either a reference or proxy object. This function always succeeds.

int PyWeakref_CheckRef(ob)

Return true if *ob* is a reference object. This function always succeeds.

int PyWeakref_CheckProxy(ob)

Return true if *ob* is a proxy object. This function always succeeds.

PyObject *PyWeakref_NewRef(PyObject *ob, PyObject *callback)

Return value: New reference. Part of the Stable ABI.
Return a weak reference object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise **`TypeError`**.

PyObject *PyWeakref_NewProxy(PyObject *ob, PyObject *callback)

Return value: New reference. Part of the Stable ABI.
Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise **`TypeError`**.

PyObject *PyWeakref_GetObject(PyObject *ref)

Return value: Borrowed reference. Part of the Stable ABI.
Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns **`Py_None`**.

Note

This function returns a borrowed reference to the referenced object. This means that you should always call **`Py_INCREF()`** on the object except when it cannot be destroyed before the last usage of the borrowed reference.

PyObject *PyWeakref_GET_OBJECT(PyObject *ref)

Return value: Borrowed reference.
Similar to **`PyWeakref_GetObject()`**, but does no error checking.

Capsules

Refer to Providing a C API for an Extension Module for more information on using these objects.

New in version 3.1.

type PyCapsule

This subtype of **PyObject** represents an opaque value, useful for C extension modules who need to pass an opaque value (as a void* pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

type PyCapsule_Destructor

Part of the Stable ABI.
The type of a destructor callback for a capsule. Defined as:

```
typedef void (*PyCapsule_Destructor)(PyObject *);
```

See **PyCapsule_New()** for the semantics of PyCapsule_Destructor callbacks.

int PyCapsule_CheckExact(PyObject *p)

Return true if its argument is a **PyCapsule**. This function always succeeds.

PyObject *PyCapsule_New(void *pointer, const char *name, PyCapsule_Destructor destructor)

Return value: New reference. Part of the Stable ABI.
Create a **PyCapsule** encapsulating the *pointer*. The *pointer* argument may not be `NULL`.

On failure, set an exception and return `NULL`.

The *name* string may either be `NULL` or a pointer to a valid C string. If non-`NULL`, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor*.)

If the *destructor* argument is not `NULL`, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as `modulename.attributename`. This will enable other modules to import the capsule using **`PyCapsule_Import()`**.

void *PyCapsule_GetPointer(PyObject *capsule, const char *name)

Part of the Stable ABI.
Retrieve the *pointer* stored in the capsule. On failure, set an exception and return `NULL`.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is `NULL`, the *name* passed in must also be `NULL`. Python uses the C function **`strcmp()`** to compare capsule names.

PyCapsule_Destructor PyCapsule_GetDestructor(PyObject *capsule)

Part of the Stable ABI.
Return the current destructor stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` destructor. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

void *PyCapsule_GetContext(PyObject *capsule)

Part of the Stable ABI.
Return the current context stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` context. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

const char *PyCapsule_GetName(PyObject *capsule)

Part of the Stable ABI.
Return the current name stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` name. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

void *PyCapsule_Import(const char *name, int no_block)

Part of the Stable ABI.
Import a pointer to a C object from a capsule attribute in a module. The *name* parameter should specify the full name to the attribute, as in `module.attribute`. The *name* stored in the capsule must match this string exactly.

Return the capsule's internal *pointer* on success. On failure, set an exception and return `NULL`.

Changed in version 3.3: no_block has no effect anymore.

int PyCapsule_IsValid(PyObject *capsule, const char *name)

Part of the Stable ABI.
Determines whether or not *capsule* is a valid capsule. A valid capsule is non-`NULL`, passes **`PyCapsule_CheckExact()`**, has a non-`NULL` pointer stored in it, and its internal name matches the *name* parameter. (See **`PyCapsule_GetPointer()`** for information on how capsule names are compared.)

In other words, if **`PyCapsule_IsValid()`** returns a true value, calls to any of the accessors (any function starting with **`PyCapsule_Get()`**) are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return `0` otherwise. This function will not fail.

int PyCapsule_SetContext(PyObject *capsule, void *context)

Part of the Stable ABI.
Set the context pointer inside *capsule* to *context*.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetDestructor(PyObject *capsule, PyCapsule_Destructor destructor)

Part of the Stable ABI.
Set the destructor inside *capsule* to *destructor*.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetName(PyObject *capsule, const char *name)

Part of the Stable ABI.
Set the name inside *capsule* to *name*. If non-`NULL`, the name must outlive the capsule. If the previous *name* stored in the capsule was not `NULL`, no attempt is made to free it.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetPointer(PyObject *capsule, void *pointer)

Part of the Stable ABI.
Set the void pointer inside *capsule* to *pointer*. The pointer may not be `NULL`.

Return `0` on success. Return nonzero and set an exception on failure.

Frame Objects

type PyFrameObject

Part of the Limited API (as an opaque struct).
The C structure of the objects used to describe frame objects.

There are no public members in this structure.

Changed in version 3.11: The members of this structure were removed from the public C API. Refer to the What's New entry for details.

The **PyEval_GetFrame()** and **PyThreadState_GetFrame()** functions can be used to get a frame object.

See also Reflection.

PyTypeObject PyFrame_Type

The type of frame objects. It is the same object as **types.FrameType** in the Python layer.

Changed in version 3.11: Previously, this type was only available after including `<frameobject.h>`.

int PyFrame_Check(PyObject *obj)

Return non-zero if *obj* is a frame object.

Changed in version 3.11: Previously, this function was only available after including `<frameobject.h>`.

PyFrameObject *PyFrame_GetBack(PyFrameObject *frame)

Get the *frame* next outer frame.

Return a strong reference, or `NULL` if *frame* has no outer frame.

New in version 3.9.

PyObject *PyFrame_GetBuiltins(PyFrameObject *frame)

Get the *frame*'s `f_builtins` attribute.

Return a strong reference. The result cannot be `NULL`.

New in version 3.11.

PyCodeObject *PyFrame_GetCode(PyFrameObject *frame)

Part of the Stable ABI since version 3.10.
Get the *frame* code.

Return a strong reference.

The result (frame code) cannot be `NULL`.

New in version 3.9.

PyObject *PyFrame_GetGenerator(PyFrameObject *frame)

Get the generator, coroutine, or async generator that owns this frame, or `NULL` if this frame is not owned by a generator. Does not raise an exception, even if the return value is `NULL`.

Return a strong reference, or `NULL`.

New in version 3.11.

PyObject *PyFrame_GetGlobals(PyFrameObject *frame)

Get the *frame*'s `f_globals` attribute.

Return a strong reference. The result cannot be `NULL`.

New in version 3.11.

int PyFrame_GetLasti(PyFrameObject *frame)

Get the *frame*'s `f_lasti` attribute.

Returns -1 if `frame.f_lasti` is `None`.

New in version 3.11.

PyObject *PyFrame_GetLocals(PyFrameObject *frame)

Get the *frame*'s `f_locals` attribute (**`dict`**).

Return a strong reference.

New in version 3.11.

int PyFrame_GetLineNumber(PyFrameObject *frame)

Part of the Stable ABI since version 3.10.
Return the line number that *frame* is currently executing.

Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling **`PyGen_New()`** or **`PyGen_NewWithQualName()`**.

type PyGenObject

The C structure used for generator objects.

PyTypeObject PyGen_Type

The type object corresponding to generator objects.

int PyGen_Check(PyObject *ob)

Return true if *ob* is a generator object; *ob* must not be `NULL`. This function always succeeds.

int PyGen_CheckExact(PyObject *ob)

Return true if *ob*'s type is **`PyGen_Type`**; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyGen_New(PyFrameObject *frame)

Return value: New reference.
Create and return a new generator object based on the *frame* object. A reference to *frame* is stolen by this function. The argument must not be `NULL`.

PyObject *PyGen_NewWithQualName(PyFrameObject *frame, PyObject *name, PyObject *qualname)

Return value: New reference.
Create and return a new generator object based on the *frame* object, with `__name__` and `__qualname__` set to *name* and *qualname*. A reference to *frame* is stolen by this function. The

frame argument must not be `NULL`.

Coroutine Objects

New in version 3.5.

Coroutine objects are what functions declared with an `async` keyword return.

type PyCoroObject

The C structure used for coroutine objects.

PyTypeObject PyCoro_Type

The type object corresponding to coroutine objects.

int PyCoro_CheckExact(PyObject *ob)

Return true if *ob*'s type is **`PyCoro_Type`**; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyCoro_New(PyFrameObject *frame, PyObject *name, PyObject *qualname)

Return value: New reference.
Create and return a new coroutine object based on the *frame* object, with `__name__` and `__qualname__` set to *name* and *qualname*. A reference to *frame* is stolen by this function. The *frame* argument must not be `NULL`.

Context Variables Objects

Changed in version 3.7.1:

Note

In Python 3.7.1 the signatures of all context variables C APIs were **changed** to use `PyObject` pointers instead of `PyContext`, `PyContextVar`, and `PyContextToken`, e.g.:

```
// in 3.7.0:
PyContext *PyContext_New(void);

// in 3.7.1+:
PyObject *PyContext_New(void);
```

See bpo-34762 [https://bugs.python.org/issue?@action=redirect&bpo=34762] for more details.

New in version 3.7.

This section details the public C API for the `contextvars` module.

type PyContext

The C structure used to represent a `contextvars.Context` object.

type PyContextVar

The C structure used to represent a `contextvars.ContextVar` object.

type PyContextToken

The C structure used to represent a `contextvars.Token` object.

PyTypeObject PyContext_Type

The type object representing the *context* type.

PyTypeObject PyContextVar_Type

The type object representing the *context variable* type.

PyTypeObject PyContextToken_Type

The type object representing the *context variable token* type.

Type-check macros:

int PyContext_CheckExact(PyObject *o)

Return true if *o* is of type **PyContext_Type**. *o* must not be `NULL`. This function always succeeds.

int PyContextVar_CheckExact(PyObject *o)

Return true if *o* is of type **PyContextVar_Type**. *o* must not be `NULL`. This function always succeeds.

int PyContextToken_CheckExact(PyObject *o)

Return true if *o* is of type **PyContextToken_Type**. *o* must not be `NULL`. This function always succeeds.

Context object management functions:

PyObject *PyContext_New(void)

Return value: New reference.
Create a new empty context object. Returns `NULL` if an error has occurred.

PyObject *PyContext_Copy(PyObject *ctx)

Return value: New reference.
Create a shallow copy of the passed *ctx* context object. Returns `NULL` if an error has occurred.

PyObject *PyContext_CopyCurrent(void)

Return value: New reference.
Create a shallow copy of the current thread context. Returns `NULL` if an error has occurred.

int PyContext_Enter(PyObject *ctx)

Set *ctx* as the current context for the current thread. Returns `0` on success, and `-1` on error.

int PyContext_Exit(PyObject *ctx)

Deactivate the *ctx* context and restore the previous context as the current context for the current thread. Returns `0` on success, and `-1` on error.

Context variable functions:

PyObject *PyContextVar_New(const char *name, PyObject *def)

Return value: New reference.
Create a new `ContextVar` object. The *name* parameter is used for introspection and debug purposes. The *def* parameter specifies a default value for the context variable, or `NULL` for no default. If an error has occurred, this function returns `NULL`.

int PyContextVar_Get(PyObject *var, PyObject *default_value, PyObject **value)

Get the value of a context variable. Returns `-1` if an error has occurred during lookup, and `0` if no error occurred, whether or not a value was found.

If the context variable was found, *value* will be a pointer to it. If the context variable was *not* found, *value* will point to:

- *default_value*, if not `NULL`;
- the default value of *var*, if not `NULL`;
- `NULL`

Except for `NULL`, the function returns a new reference.

PyObject *PyContextVar_Set(PyObject *var, PyObject *value)

Return value: New reference.
Set the value of *var* to *value* in the current context. Returns a new token object for this change, or `NULL` if an error has occurred.

int PyContextVar_Reset(PyObject *var, PyObject *token)

Reset the state of the *var* context variable to that it was in before **`PyContextVar_Set()`** that returned the *token* was called. This function returns `0` on success and `-1` on error.

DateTime Objects

Various date and time objects are supplied by the **datetime** module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro **PyDateTime_IMPORT** must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, **PyDateTimeAPI**, that is used by the following macros.

Macro for access to the UTC singleton:

PyObject *PyDateTime_TimeZone_UTC

Returns the time zone singleton representing UTC, the same object as **datetime.timezone.utc**.

New in version 3.7.

Type-check macros:

int PyDate_Check(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DateType** or a subtype of **PyDateTime_DateType**. *ob* must not be `NULL`. This function always succeeds.

int PyDate_CheckExact(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DateType**. *ob* must not be `NULL`. This function always succeeds.

int PyDateTime_Check(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DateTimeType** or a subtype of **PyDateTime_DateTimeType**. *ob* must not be `NULL`. This function always succeeds.

int PyDateTime_CheckExact(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DateTimeType**. *ob* must not be NULL. This function always succeeds.

int PyTime_Check(PyObject *ob)

Return true if *ob* is of type **PyDateTime_TimeType** or a subtype of **PyDateTime_TimeType**. *ob* must not be NULL. This function always succeeds.

int PyTime_CheckExact(PyObject *ob)

Return true if *ob* is of type **PyDateTime_TimeType**. *ob* must not be NULL. This function always succeeds.

int PyDelta_Check(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DeltaType** or a subtype of **PyDateTime_DeltaType**. *ob* must not be NULL. This function always succeeds.

int PyDelta_CheckExact(PyObject *ob)

Return true if *ob* is of type **PyDateTime_DeltaType**. *ob* must not be NULL. This function always succeeds.

int PyTZInfo_Check(PyObject *ob)

Return true if *ob* is of type **PyDateTime_TZInfoType** or a subtype of **PyDateTime_TZInfoType**. *ob* must not be NULL. This function always succeeds.

int PyTZInfo_CheckExact(PyObject *ob)

Return true if *ob* is of type **PyDateTime_TZInfoType**. *ob* must not be NULL. This function always succeeds.

Macros to create objects:

PyObject *PyDate_FromDate(int year, int month, int day)

Return value: New reference.
Return a **datetime.date** object with the specified year,

month and day.

PyObject *PyDateTime_FromDateAndTime(int year, int month, int day, int hour, int minute, int second, int usecond)

Return value: New reference.
Return a **datetime.datetime** object with the specified year, month, day, hour, minute, second and microsecond.

PyObject *PyDateTime_FromDateAndTimeAndFold(int year, int month, int day, int hour, int minute, int second, int usecond, int fold)

Return value: New reference.
Return a **datetime.datetime** object with the specified year, month, day, hour, minute, second, microsecond and fold.

New in version 3.6.

PyObject *PyTime_FromTime(int hour, int minute, int second, int usecond)

Return value: New reference.
Return a **datetime.time** object with the specified hour, minute, second and microsecond.

PyObject *PyTime_FromTimeAndFold(int hour, int minute, int second, int usecond, int fold)

Return value: New reference.
Return a **datetime.time** object with the specified hour, minute, second, microsecond and fold.

New in version 3.6.

PyObject *PyDelta_FromDSU(int days, int seconds, int useconds)

Return value: New reference.
Return a **datetime.timedelta** object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of

microseconds and seconds lie in the ranges documented for **datetime.timedelta** objects.

PyObject *PyTimeZone_FromOffset(PyDateTime_DeltaType *offset)

Return value: New reference.
Return a **datetime.timezone** object with an unnamed fixed offset represented by the *offset* argument.

New in version 3.7.

PyObject *PyTimeZone_FromOffsetAndName(PyDateTime_DeltaType *offset, PyUnicode *name)

Return value: New reference.
Return a **datetime.timezone** object with a fixed offset represented by the *offset* argument and with tzname *name*.

New in version 3.7.

Macros to extract fields from date objects. The argument must be an instance of **PyDateTime_Date**, including subclasses (such as **PyDateTime_DateTime**). The argument must not be `NULL`, and the type is not checked:

int PyDateTime_GET_YEAR(PyDateTime_Date *o)

Return the year, as a positive int.

int PyDateTime_GET_MONTH(PyDateTime_Date *o)

Return the month, as an int from 1 through 12.

int PyDateTime_GET_DAY(PyDateTime_Date *o)

Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of **PyDateTime_DateTime**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)
Return the hour, as an int from 0 through 23.

int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)
Return the minute, as an int from 0 through 59.

int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)
Return the second, as an int from 0 through 59.

int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)
Return the microsecond, as an int from 0 through 999999.

int PyDateTime_DATE_GET_FOLD(PyDateTime_DateTime *o)
Return the fold, as an int from 0 through 1.

New in version 3.6.

PyObject *PyDateTime_DATE_GET_TZINFO(PyDateTime_DateTime *o)
Return the tzinfo (which may be `None`).

New in version 3.10.

Macros to extract fields from time objects. The argument must be an instance of **`PyDateTime_Time`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)
Return the hour, as an int from 0 through 23.

int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)
Return the minute, as an int from 0 through 59.

int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)

Return the second, as an int from 0 through 59.

int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)
Return the microsecond, as an int from 0 through 999999.

int PyDateTime_TIME_GET_FOLD(PyDateTime_Time *o)
Return the fold, as an int from 0 through 1.

New in version 3.6.

PyObject *PyDateTime_TIME_GET_TZINFO(PyDateTime_Time *o)
Return the tzinfo (which may be `None`).

New in version 3.10.

Macros to extract fields from time delta objects. The argument must be an instance of **`PyDateTime_Delta`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_DELTA_GET_DAYS(PyDateTime_Delta *o)
Return the number of days, as an int from -999999999 to 999999999.

New in version 3.3.

int PyDateTime_DELTA_GET_SECONDS(PyDateTime_Delta *o)
Return the number of seconds, as an int from 0 through 86399.

New in version 3.3.

int PyDateTime_DELTA_GET_MICROSECONDS(PyDateTime_Delta *o)
Return the number of microseconds, as an int from 0 through 999999.

New in version 3.3.

Macros for the convenience of modules implementing the DB API:

PyObject *PyDateTime_FromTimestamp(PyObject *args)

Return value: New reference.
Create and return a new **`datetime.datetime`** object given an argument tuple suitable for passing to **`datetime.datetime.fromtimestamp()`**.

PyObject *PyDate_FromTimestamp(PyObject *args)

Return value: New reference.
Create and return a new **`datetime.date`** object given an argument tuple suitable for passing to **`datetime.date.fromtimestamp()`**.

Objects for Type Hinting

Various built-in types for type hinting are provided. Currently, two types exist – GenericAlias and Union. Only `GenericAlias` is exposed to C.

PyObject *Py_GenericAlias(PyObject *origin, PyObject *args)

Part of the Stable ABI since version 3.9.
Create a GenericAlias object. Equivalent to calling the Python class **`types.GenericAlias`**. The *origin* and *args* arguments set the `GenericAlias`'s `__origin__` and `__args__` attributes respectively. *origin* should be a PyTypeObject*, and *args* can be a PyTupleObject* or any `PyObject*`. If *args* passed is not a tuple, a 1-tuple is automatically constructed and `__args__` is set to `(args,)`. Minimal checking is done for the arguments, so the function will succeed even if *origin* is not a type. The `GenericAlias`'s `__parameters__` attribute is constructed lazily from `__args__`. On failure, an exception is raised and `NULL` is returned.

Here's an example of how to make an extension type generic:

```
...
static PyMethodDef my_obj_methods[] = {
    // Other methods.
    ...
    {"__class_getitem__", Py_GenericAlias, METH_O|M
    ...
}
```

See also

The data model method **`__class_getitem__()`**.

New in version 3.9.

PyTypeObject Py_GenericAliasType

Part of the Stable ABI since version 3.9.
The C type of the object returned by `Py_GenericAlias()`. Equivalent to `types.GenericAlias` in Python.

New in version 3.9.

Initialization, Finalization, and Threads

See also Python Initialization Configuration.

Before Python Initialization

In an application embedding Python, the **`Py_Initialize()`** function must be called before using any other Python/C API functions; with the exception of a few functions and the global configuration variables.

The following functions can be safely called before Python is initialized:

- Configuration functions:
  - **`PyImport_AppendInittab()`**
  - **`PyImport_ExtendInittab()`**
  - **`PyInitFrozenExtensions()`**
  - **`PyMem_SetAllocator()`**
  - **`PyMem_SetupDebugHooks()`**
  - **`PyObject_SetArenaAllocator()`**
  - **`Py_SetPath()`**
  - **`Py_SetProgramName()`**
  - **`Py_SetPythonHome()`**
  - **`Py_SetStandardStreamEncoding()`**
  - **`PySys_AddWarnOption()`**
  - **`PySys_AddXOption()`**
  - **`PySys_ResetWarnOptions()`**
- Informative functions:
  - **`Py_IsInitialized()`**
  - **`PyMem_GetAllocator()`**
  - **`PyObject_GetArenaAllocator()`**
  - **`Py_GetBuildInfo()`**
  - **`Py_GetCompiler()`**

    - **Py_GetCopyright()**
    - **Py_GetPlatform()**
    - **Py_GetVersion()**
- Utilities:
    - **Py_DecodeLocale()**
- Memory allocators:
    - **PyMem_RawMalloc()**
    - **PyMem_RawRealloc()**
    - **PyMem_RawCalloc()**
    - **PyMem_RawFree()**

Note

The following functions **should not be called** before **Py_Initialize()**: **Py_EncodeLocale()**, **Py_GetPath()**, **Py_GetPrefix()**, **Py_GetExecPrefix()**, **Py_GetProgramFullPath()**, **Py_GetPythonHome()**, **Py_GetProgramName()** and **PyEval_InitThreads()**.

Global configuration variables

Python has variables for the global configuration to control different features and options. By default, these flags are controlled by command line options.

When a flag is set by an option, the value of the flag is the number of times that the option was set. For example, `-b` sets **Py_BytesWarningFlag** to 1 and `-bb` sets **Py_BytesWarningFlag** to 2.

int Py_BytesWarningFlag

Issue a warning when comparing **bytes** or **bytearray** with **str** or **bytes** with **int**. Issue an error if greater or equal to `2`.

Set by the **-b** option.

int Py_DebugFlag

Turn on parser debugging output (for expert only, depending

on compilation options).

Set by the **-d** option and the **PYTHONDEBUG** environment variable.

int Py_DontWriteBytecodeFlag

If set to non-zero, Python won't try to write `.pyc` files on the import of source modules.

Set by the **-B** option and the **PYTHONDONTWRITEBYTECODE** environment variable.

int Py_FrozenFlag

Suppress error messages when calculating the module search path in **Py_GetPath()**.

Private flag used by `_freeze_module` and `frozenmain` programs.

int Py_HashRandomizationFlag

Set to `1` if the **PYTHONHASHSEED** environment variable is set to a non-empty string.

If the flag is non-zero, read the **PYTHONHASHSEED** environment variable to initialize the secret hash seed.

int Py_IgnoreEnvironmentFlag

Ignore all **PYTHON*** environment variables, e.g. **PYTHONPATH** and **PYTHONHOME**, that might be set.

Set by the **-E** and **-I** options.

int Py_InspectFlag

When a script is passed as first argument or the **-c** option is used, enter interactive mode after executing the script or the command, even when **sys.stdin** does not appear to be a terminal.

Set by the **-i** option and the **PYTHONINSPECT** environment

variable.

int Py_InteractiveFlag
: Set by the **-i** option.

int Py_IsolatedFlag
: Run Python in isolated mode. In isolated mode **sys.path** contains neither the script's directory nor the user's site-packages directory.

  Set by the **-I** option.

  New in version 3.4.

int Py_LegacyWindowsFSEncodingFlag
: If the flag is non-zero, use the `mbcs` encoding with `replace` error handler, instead of the UTF-8 encoding with `surrogatepass` error handler, for the filesystem encoding and error handler.

  Set to `1` if the **PYTHONLEGACYWINDOWSFSENCODING** environment variable is set to a non-empty string.

  See **PEP 529** [https://peps.python.org/pep-0529/] for more details.

  Availability: Windows.

int Py_LegacyWindowsStdioFlag
: If the flag is non-zero, use **io.FileIO** instead of **WindowsConsoleIO** for **sys** standard streams.

  Set to `1` if the **PYTHONLEGACYWINDOWSSTDIO** environment variable is set to a non-empty string.

  See **PEP 528** [https://peps.python.org/pep-0528/] for more details.

  Availability: Windows.

int Py_NoSiteFlag

Disable the import of the module **site** and the site-dependent manipulations of **sys.path** that it entails. Also disable these manipulations if **site** is explicitly imported later (call **site.main()** if you want them to be triggered).

Set by the **-S** option.

int Py_NoUserSiteDirectory

Don't add the **user site-packages directory** to **sys.path**.

Set by the **-s** and **-I** options, and the **PYTHONNOUSERSITE** environment variable.

int Py_OptimizeFlag

Set by the **-O** option and the **PYTHONOPTIMIZE** environment variable.

int Py_QuietFlag

Don't display the copyright and version messages even in interactive mode.

Set by the **-q** option.

New in version 3.2.

int Py_UnbufferedStdioFlag

Force the stdout and stderr streams to be unbuffered.

Set by the **-u** option and the **PYTHONUNBUFFERED** environment variable.

int Py_VerboseFlag

Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. If greater or equal to `2`, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Set by the **-v** option and the **PYTHONVERBOSE** environment variable.

Initializing and finalizing the interpreter

void Py_Initialize()

Part of the Stable ABI.
Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; see Before Python Initialization for the few exceptions.

This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules **builtins**, **__main__** and **sys**. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use **PySys_SetArgvEx()** for that. This is a no-op when called for a second time (without calling **Py_FinalizeEx()** first). There is no return value; it is a fatal error if the initialization fails.

Note

On Windows, changes the console mode from `O_TEXT` to `O_BINARY`, which will also affect non-Python uses of the console using the C Runtime.

void Py_InitializeEx(int initsigs)

Part of the Stable ABI.
This function works like **Py_Initialize()** if *initsigs* is `1`. If *initsigs* is `0`, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

int Py_IsInitialized()

Part of the Stable ABI.
Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After **Py_FinalizeEx()** is

called, this returns false until **Py_Initialize()** is called again.

int Py_FinalizeEx()

Part of the Stable ABI since version 3.6.
Undo all initializations made by **Py_Initialize()** and subsequent use of Python/C API functions, and destroy all sub-interpreters (see **Py_NewInterpreter()** below) that were created and not yet destroyed since the last call to **Py_Initialize()**. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling **Py_Initialize()** again first). Normally the return value is `0`. If there were errors during finalization (flushing buffered data), `-1` is returned.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

Bugs and caveats: The destruction of modules and objects in modules is done in random order; this may cause destructors (**__del__()** methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls **Py_Initialize()** and **Py_FinalizeEx()** more than once.

Raises an auditing event

`cpython._PySys_ClearAuditHooks` with no arguments.

New in version 3.6.

void Py_Finalize()

Part of the Stable ABI.
This is a backwards-compatible version of **`Py_FinalizeEx()`** that disregards the return value.

Process-wide parameters

int Py_SetStandardStreamEncoding(const char *encoding, const char *errors)

This API is kept for backward compatibility: setting **`PyConfig.stdio_encoding`** and **`PyConfig.stdio_errors`** should be used instead, see Python Initialization Configuration.

This function should be called before **`Py_Initialize()`**, if it is called at all. It specifies which encoding and error handling to use with standard IO, with the same meanings as in **`str.encode()`**.

It overrides **`PYTHONIOENCODING`** values, and allows embedding code to control IO encoding when the environment variable does not work.

encoding and/or *errors* may be `NULL` to use **`PYTHONIOENCODING`** and/or default values (depending on other settings).

Note that **`sys.stderr`** always uses the “backslashreplace” error handler, regardless of this (or any other) setting.

If **`Py_FinalizeEx()`** is called, this function will need to be called again in order to affect subsequent calls to **`Py_Initialize()`**.

Returns `0` if successful, a nonzero value on error (e.g. calling

after the interpreter has already been initialized).

New in version 3.4.

Deprecated since version 3.11.

void Py_SetProgramName(const wchar_t *name)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.program_name** should be used instead, see Python Initialization Configuration.

This function should be called before **Py_Initialize()** is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the **main()** function of the program (converted to wide characters). This is used by **Py_GetPath()** and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `'python'`. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use **Py_DecodeLocale()** to decode a bytes string to get a wchar_* string.

Deprecated since version 3.11.

wchar *Py_GetProgramName()

Part of the Stable ABI.
Return the program name set with **Py_SetProgramName()**, or the default. The returned string points into static storage; the caller should not modify its value.

This function should not be called before **Py_Initialize()**, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before

Py_Initialize().

wchar_t *Py_GetPrefix()

Part of the Stable ABI.
Return the *prefix* for installed platform-independent files. This is derived through a number of complicated rules from the program name set with **Py_SetProgramName()** and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **prefix** variable in the top-level `Makefile` and the `--prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.prefix`. It is only useful on Unix. See also the next function.

This function should not be called before **Py_Initialize()**, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before **Py_Initialize()**.

wchar_t *Py_GetExecPrefix()

Part of the Stable ABI.
Return the *exec-prefix* for installed platform-*dependent* files. This is derived through a number of complicated rules from the program name set with **Py_SetProgramName()** and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the exec-prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **exec_prefix** variable in the top-level `Makefile` and the `--exec-prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared

libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the **mount** or **automount** programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.

This function should not be called before **`Py_Initialize()`**, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before **`Py_Initialize()`**.

wchar_t *Py_GetProgramFullPath()

Part of the Stable ABI.
Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by **`Py_SetProgramName()`** above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

This function should not be called before

Py_Initialize(), otherwise it returns NULL.

Changed in version 3.10: It now returns NULL if called before **Py_Initialize()**.

wchar_t *Py_GetPath()

Part of the Stable ABI.
Return the default module search path; this is computed from the program name (set by **Py_SetProgramName()** above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is ':' on Unix and macOS, ';' on Windows. The returned string points into static storage; the caller should not modify its value. The list **sys.path** is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

This function should not be called before **Py_Initialize()**, otherwise it returns NULL.

Changed in version 3.10: It now returns NULL if called before **Py_Initialize()**.

void Py_SetPath(const wchar_t*)

Part of the Stable ABI since version 3.7.
This API is kept for backward compatibility: setting **PyConfig.module_search_paths** and **PyConfig.module_search_paths_set** should be used instead, see Python Initialization Configuration.

Set the default module search path. If this function is called before **Py_Initialize()**, then **Py_GetPath()** won't attempt to compute a default search path but uses the one provided instead. This is useful if Python is embedded by an application that has full knowledge of the location of all modules. The path components should be separated by the platform dependent delimiter character, which is ':' on Unix and macOS, ';' on Windows.

This also causes **sys.executable** to be set to the program full path (see **Py_GetProgramFullPath()**) and for **sys.prefix** and **sys.exec_prefix** to be empty. It is up to the caller to modify these if required after calling **Py_Initialize()**.

Use **Py_DecodeLocale()** to decode a bytes string to get a wchar_* string.

The path argument is copied internally, so the caller may free it after the call completes.

Changed in version 3.8: The program full path is now used for **sys.executable**, instead of the program name.

Deprecated since version 3.11.

const char *Py_GetVersion()

Part of the Stable ABI.
Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n[GCC
```

The first word (up to the first space character) is the current Python version; the first characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as **sys.version**.

See also the **Py_Version** constant.

const char *Py_GetPlatform()

Part of the Stable ABI.
Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is `'sunos5'`. On macOS, it is `'darwin'`. On Windows, it is `'win'`. The returned string

points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

const char *Py_GetCopyright()

Part of the Stable ABI.
Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch
Centrum, Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

const char *Py_GetCompiler()

Part of the Stable ABI.
Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

const char *Py_GetBuildInfo()

Part of the Stable ABI.
Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug  1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

void PySys_SetArgvEx(int argc, wchar_t **argv, int updatepath)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.argv**, **PyConfig.parse_argv** and **PyConfig.safe_path** should be used instead, see Python Initialization Configuration.

Set **sys.argv** based on *argc* and *argv*. These parameters are similar to those passed to the program's **main()** function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in *argv* can be an empty string. If this function fails to initialize **sys.argv**, a fatal condition is signalled using **Py_FatalError()**.

If *updatepath* is zero, this is all the function does. If *updatepath* is non-zero, the function also modifies **sys.path** according to the following algorithm:

- If the name of an existing script is passed in `argv[0]`, the absolute path of the directory where the script is located is prepended to **sys.path**.
- Otherwise (that is, if *argc* is `0` or `argv[0]` doesn't point to an existing file name), an empty string is prepended to **sys.path**, which is the same as prepending the current working directory (`"."`).

Use **Py_DecodeLocale()** to decode a bytes string to get a wchar_* string.

See also **PyConfig.orig_argv** and **PyConfig.argv** members of the Python Initialization Configuration.

Note

It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass `0` as *updatepath*, and update **sys.path** themselves if desired. See CVE-2008-5983 [https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2008-5983].

On versions before 3.1.3, you can achieve the same effect by manually popping the first **sys.path** element after having called **PySys_SetArgv()**, for example using:

```
PyRun_SimpleString("import sys; sys.path.pop(0)\n"
```

New in version 3.1.3.

Deprecated since version 3.11.

void PySys_SetArgv(int argc, wchar_t **argv)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.argv** and **PyConfig.parse_argv** should be used instead, see Python Initialization Configuration.

This function works like **PySys_SetArgvEx()** with *updatepath* set to `1` unless the **python** interpreter was started with the **-I**.

Use **Py_DecodeLocale()** to decode a bytes string to get a wchar_* string.

See also **PyConfig.orig_argv** and **PyConfig.argv** members of the Python Initialization Configuration.

Changed in version 3.4: The *updatepath* value depends on **-I**.

Deprecated since version 3.11.

void Py_SetPythonHome(const wchar_t *home)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **PyConfig.home** should be used instead, see Python Initialization Configuration.

Set the default “home” directory, that is, the location of the standard Python libraries. See **PYTHONHOME** for the meaning of the argument string.

The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use **Py_DecodeLocale()** to decode a bytes string to get a wchar_* string.

Deprecated since version 3.11.

w_char *Py_GetPythonHome()

Part of the Stable ABI.
Return the default "home", that is, the value set by a previous call to **Py_SetPythonHome()**, or the value of the **PYTHONHOME** environment variable if it is set.

This function should not be called before **Py_Initialize()**, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before **Py_Initialize()**.

Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there's a global lock, called the global interpreter lock or GIL, that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the GIL may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see **sys.setswitchinterval()**). The lock is also released around

potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called **`PyThreadState`**. There's also one global variable pointing to the current **`PyThreadState`**: it can be retrieved using **`PyThreadState_Get()`**.

Releasing the GIL from extension code

Most extension code manipulating the GIL has the following simple structure:

```
Save the thread state in a local variable.
Release the global interpreter lock.
... Do some blocking I/O operation ...
Reacquire the global interpreter lock.
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS
... Do some blocking I/O operation ...
Py_END_ALLOW_THREADS
```

The **`Py_BEGIN_ALLOW_THREADS`** macro opens a new block and declares a hidden local variable; the **`Py_END_ALLOW_THREADS`** macro closes the block.

The block above expands to the following code:

```
PyThreadState *_save;

_save = PyEval_SaveThread();
... Do some blocking I/O operation ...
PyEval_RestoreThread(_save);
```

Here is how these functions work: the global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer

must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

Note

Calling system I/O functions is the most common use case for releasing the GIL, but it can also be useful before calling long-running computations which don't need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard **zlib** and **hashlib** modules release the GIL when compressing or hashing data.

Non-Python created threads

When threads are created using the dedicated Python APIs (such as the **threading** module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don't hold the GIL, nor is there a thread state structure for them.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating a thread state data structure, then acquiring the GIL, and finally storing their thread state pointer, before you can start using the Python/C API. When you are done, you should reset the thread state pointer, release the GIL, and finally free the thread state data structure.

The **PyGILState_Ensure()** and **PyGILState_Release()** functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();
```

```
/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result or handle exception */

/* Release the thread. No Python API allowed beyond this
PyGILState_Release(gstate);
```

Note that the `PyGILState_*` functions assume there is only one global interpreter (created automatically by **`Py_Initialize()`**). Python supports the creation of additional interpreters (using **`Py_NewInterpreter()`**), but mixing multiple interpreters and the `PyGILState_*` API is unsupported.

Cautions about fork()

Another important thing to note about threads is their behaviour in the face of the C **`fork()`** call. On most systems with **`fork()`**, after a process forks only the thread that issued the fork will exist. This has a concrete impact both on how locks must be handled and on all stored state in CPython's runtime.

The fact that only the "current" thread remains means any locks held by other threads will never be released. Python solves this for **`os.fork()`** by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any Lock Objects in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as **`pthread_atfork()`** would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling **`fork()`** directly rather than through **`os.fork()`** (and returning to or calling into Python) may result in a deadlock by one of Python's internal locks being held by a thread that is defunct after the fork. **`PyOS_AfterFork_Child()`** tries to reset the necessary locks, but is not always able to.

The fact that all other threads go away also means that CPython's runtime state there must be cleaned up properly, which **`os.fork()`** does. This means finalizing all other **`PyThreadState`**

objects belonging to the current interpreter and all other **PyInterpreterState** objects. Due to this and the special nature of the "main" interpreter, **fork()** should only be called in that interpreter's "main" thread, where the CPython global runtime was originally initialized. The only exception is if **exec()** will be called immediately after.

High-level API

These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

type PyInterpreterState

Part of the Limited API (as an opaque struct).
This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

type PyThreadState

Part of the Limited API (as an opaque struct).
This data structure represents the state of a single thread. The only public data member is **interp** (PyInterpreterState*), which points to this thread's interpreter state.

void PyEval_InitThreads()

Part of the Stable ABI.
Deprecated function which does nothing.

In Python 3.6 and older, this function created the GIL if it didn't exist.

Changed in version 3.9: The function now does nothing.

Changed in version 3.7: This function is now called by **Py_Initialize()**, so you don't have to call it yourself anymore.

Changed in version 3.2: This function cannot be called before **Py_Initialize()** anymore.

Deprecated since version 3.9, removed in version 3.11.

int PyEval_ThreadsInitialized()

Part of the Stable ABI.
Returns a non-zero value if **PyEval_InitThreads()** has been called. This function can be called without holding the GIL, and therefore can be used to avoid calls to the locking API when running single-threaded.

Changed in version 3.7: The GIL is now initialized by **Py_Initialize()**.

Deprecated since version 3.9, removed in version 3.11.

PyThreadState *PyEval_SaveThread()

Part of the Stable ABI.
Release the global interpreter lock (if it has been created) and reset the thread state to `NULL`, returning the previous thread state (which is not `NULL`). If the lock has been created, the current thread must have acquired it.

void PyEval_RestoreThread(PyThreadState *tstate)

Part of the Stable ABI.
Acquire the global interpreter lock (if it has been created) and set the thread state to *tstate*, which must not be `NULL`. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues.

Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use **`_Py_IsFinalizing()`** or **`sys.is_finalizing()`** to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

PyThreadState *PyThreadState_Get()

Part of the Stable ABI.
Return the current thread state. The global interpreter lock must be held. When the current thread state is `NULL`, this issues a fatal error (so that the caller needn't check for `NULL`).

PyThreadState *PyThreadState_Swap(PyThreadState *tstate)

Part of the Stable ABI.
Swap the current thread state with the thread state given by the argument *tstate*, which may be `NULL`. The global interpreter lock must be held and is not released.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

PyGILState_STATE PyGILState_Ensure()

Part of the Stable ABI.
Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to **`PyGILState_Release()`**. In general, other thread-related APIs may be used between **`PyGILState_Ensure()`** and **`PyGILState_Release()`** calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the **`Py_BEGIN_ALLOW_THREADS`** and **`Py_END_ALLOW_THREADS`** macros is acceptable.

The return value is an opaque “handle” to the thread state when **PyGILState_Ensure()** was called, and must be passed to **PyGILState_Release()** to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to **PyGILState_Ensure()** must save the handle for its call to **PyGILState_Release()**.

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use **_Py_IsFinalizing()** or **sys.is_finalizing()** to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

void PyGILState_Release(PyGILState_STATE)

Part of the Stable ABI.
Release any resources previously acquired. After this call, Python’s state will be the same as it was prior to the corresponding **PyGILState_Ensure()** call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to **PyGILState_Ensure()** must be matched by a call to **PyGILState_Release()** on the same thread.

PyThreadState *PyGILState_GetThisThreadState()

Part of the Stable ABI.
Get the current thread state for this thread. May return `NULL` if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread.

This is mainly a helper/diagnostic function.

int PyGILState_Check()

Return `1` if the current thread is holding the GIL and `0` otherwise. This function can be called from any thread at any time. Only if it has had its Python thread state initialized and currently is holding the GIL will it return `1`. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

New in version 3.4.

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

Py_BEGIN_ALLOW_THREADS

Part of the Stable ABI.
This macro expands to `{ PyThreadState *_save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following **`Py_END_ALLOW_THREADS`** macro. See above for further discussion of this macro.

Py_END_ALLOW_THREADS

Part of the Stable ABI.
This macro expands to `PyEval_RestoreThread(_save); }`. Note that it contains a closing brace; it must be matched with an earlier **`Py_BEGIN_ALLOW_THREADS`** macro. See above for further discussion of this macro.

Py_BLOCK_THREADS

Part of the Stable ABI.
This macro expands to `PyEval_RestoreThread(_save);`: it is equivalent to **`Py_END_ALLOW_THREADS`** without the closing brace.

Py_UNBLOCK_THREADS

Part of the Stable ABI.
This macro expands to `_save = PyEval_SaveThread();`: it is equivalent to **`Py_BEGIN_ALLOW_THREADS`** without the opening brace and variable declaration.

Low-level API

All of the following functions must be called after **`Py_Initialize()`**.

Changed in version 3.7: **`Py_Initialize()`** now initializes the GIL.

PyInterpreterState *PyInterpreterState_New()

Part of the Stable ABI.
Create a new interpreter state object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

Raises an auditing event `cpython.PyInterpreterState_New` with no arguments.

void PyInterpreterState_Clear(PyInterpreterState *interp)

Part of the Stable ABI.
Reset all information in an interpreter state object. The global interpreter lock must be held.

Raises an auditing event `cpython.PyInterpreterState_Clear` with no arguments.

void PyInterpreterState_Delete(PyInterpreterState *interp)

Part of the Stable ABI.
Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to **`PyInterpreterState_Clear()`**.

PyThreadState *PyThreadState_New(PyInterpreterState *interp)

Part of the Stable ABI.
Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

void PyThreadState_Clear(PyThreadState *tstate)

Part of the Stable ABI.
Reset all information in a thread state object. The global interpreter lock must be held.

Changed in version 3.9: This function now calls the **PyThreadState.on_delete** callback. Previously, that happened in **PyThreadState_Delete()**.

void PyThreadState_Delete(PyThreadState *tstate)

Part of the Stable ABI.
Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear()**.

void PyThreadState_DeleteCurrent(void)

Destroy the current thread state and release the global interpreter lock. Like **PyThreadState_Delete()**, the global interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear()**.

PyFrameObject *PyThreadState_GetFrame(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the current frame of the Python thread state *tstate*.

Return a strong reference. Return `NULL` if no frame is currently executing.

See also **PyEval_GetFrame()**.

tstate must not be `NULL`.

New in version 3.9.

uint64_t PyThreadState_GetID(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the unique thread state identifier of the Python thread state *tstate*.

tstate must not be `NULL`.

New in version 3.9.

PyInterpreterState *PyThreadState_GetInterpreter(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the interpreter of the Python thread state *tstate*.

tstate must not be `NULL`.

New in version 3.9.

void PyThreadState_EnterTracing(PyThreadState *tstate)

Suspend tracing and profiling in the Python thread state *tstate*.

Resume them using the **`PyThreadState_LeaveTracing()`** function.

New in version 3.11.

void PyThreadState_LeaveTracing(PyThreadState *tstate)

Resume tracing and profiling in the Python thread state *tstate* suspended by the **`PyThreadState_EnterTracing()`** function.

See also **`PyEval_SetTrace()`** and **`PyEval_SetProfile()`** functions.

New in version 3.11.

PyInterpreterState *PyInterpreterState_Get(void)

Part of the Stable ABI since version 3.9.
Get the current interpreter.

Issue a fatal error if there no current Python thread state or no current interpreter. It cannot return NULL.

The caller must hold the GIL.

New in version 3.9.

int64_t PyInterpreterState_GetID(PyInterpreterState *interp)

Part of the Stable ABI since version 3.7.
Return the interpreter's unique ID. If there was any error in doing so then `-1` is returned and an error is set.

The caller must hold the GIL.

New in version 3.7.

PyObject *PyInterpreterState_GetDict(PyInterpreterState *interp)

Part of the Stable ABI since version 3.8.
Return a dictionary in which interpreter-specific data may be stored. If this function returns `NULL` then no exception has been raised and the caller should assume no interpreter-specific dict is available.

This is not a replacement for **`PyModule_GetState()`**, which extensions should use to store interpreter-specific state information.

New in version 3.8.

typedef PyObject *(*_PyFrameEvalFunction)(PyThreadState *tstate, _PyInterpreterFrame *frame, int throwflag)

Type of a frame evaluation function.

The *throwflag* parameter is used by the `throw()` method of generators: if non-zero, handle the current exception.

Changed in version 3.9: The function now takes a *tstate* parameter.

Changed in version 3.11: The *frame* parameter changed from `PyFrameObject*` to `_PyInterpreterFrame*`.

_PyFrameEvalFunction
_PyInterpreterState_GetEvalFrameFunc(PyInterpreterState *interp)

Get the frame evaluation function.

See the **PEP 523** [https://peps.python.org/pep-0523/] "Adding a frame evaluation API to CPython".

New in version 3.9.

void _PyInterpreterState_SetEvalFrameFunc(PyInterpreterState *interp, _PyFrameEvalFunction eval_frame)

Set the frame evaluation function.

See the **PEP 523** [https://peps.python.org/pep-0523/] "Adding a frame evaluation API to CPython".

New in version 3.9.

PyObject *PyThreadState_GetDict()

Return value: Borrowed reference. Part of the Stable ABI. Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns `NULL`, no exception has been raised and the caller should assume no current thread state is available.

int PyThreadState_SetAsyncExc(unsigned long id, PyObject *exc)

Part of the Stable ABI.

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If *exc* is **NULL**, the pending exception (if any) for the thread is cleared. This raises no exceptions.

Changed in version 3.7: The type of the *id* parameter changed from long to unsigned long.

void PyEval_AcquireThread(PyThreadState *tstate)

Part of the Stable ABI.
Acquire the global interpreter lock and set the current thread state to *tstate*, which must not be `NULL`. The lock must have been created earlier. If this thread already has the lock, deadlock ensues.

Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use **_Py_IsFinalizing()** or **sys.is_finalizing()** to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

Changed in version 3.8: Updated to be consistent with **PyEval_RestoreThread()**, **Py_END_ALLOW_THREADS()**, and **PyGILState_Ensure()**, and terminate the current thread if called while the interpreter is finalizing.

PyEval_RestoreThread() is a higher-level function which is always available (even when threads have not been initialized).

void PyEval_ReleaseThread(PyThreadState *tstate)

Part of the Stable ABI.
Reset the current thread state to `NULL` and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The *tstate* argument, which must not be `NULL`, is only used to check that it represents the current thread state — if it isn't, a fatal error is reported.

`PyEval_SaveThread()` is a higher-level function which is always available (even when threads have not been initialized).

void PyEval_AcquireLock()

Part of the Stable ABI.
Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

Deprecated since version 3.2: This function does not update the current thread state. Please use **`PyEval_RestoreThread()`** or **`PyEval_AcquireThread()`** instead.

Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use **`_Py_IsFinalizing()`** or **`sys.is_finalizing()`** to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

Changed in version 3.8: Updated to be consistent with **`PyEval_RestoreThread()`**, **`Py_END_ALLOW_THREADS()`**, and **`PyGILState_Ensure()`**, and terminate the current thread if called while the interpreter is finalizing.

void PyEval_ReleaseLock()

Part of the Stable ABI.
Release the global interpreter lock. The lock must have been

created earlier.

Deprecated since version 3.2: This function does not update the current thread state. Please use **PyEval_SaveThread()** or **PyEval_ReleaseThread()** instead.

Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that.

The "main" interpreter is the first one created when the runtime initializes. It is usually the only Python interpreter in a process. Unlike sub-interpreters, the main interpreter has unique process-global responsibilities like signal handling. It is also responsible for execution during runtime initialization and is usually the active interpreter during runtime finalization. The **PyInterpreterState_Main()** function returns a pointer to its state.

You can switch between sub-interpreters using the **PyThreadState_Swap()** function. You can create and destroy them using the following functions:

PyThreadState *Py_NewInterpreter()

Part of the Stable ABI.
Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules **builtins**, **__main__** and **sys**. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The return value points to the first thread state created in the

new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, `NULL` is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn't be a current thread state on entry.)

Extension modules are shared between (sub-)interpreters as follows:

- For modules using multi-phase initialization, e.g. **`PyModule_FromDefAndSpec()`**, a separate module object is created and initialized for each interpreter. Only C-level static and global variables are shared between these module objects.

- For modules using single-phase initialization, e.g. **`PyModule_Create()`**, the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Objects in the module's dictionary thus end up shared across (sub-)interpreters, which might cause unwanted behavior (see Bugs and caveats below).

  Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling **`Py_FinalizeEx()`** and **`Py_Initialize()`**; in that case, the extension's `initmodule` function *is* called again. As with multi-phase initialization, this means that only C-level static and global variables are shared between these modules.

void Py_EndInterpreter(PyThreadState *tstate)

Part of the Stable ABI.
Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) **`Py_FinalizeEx()`** will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like **`os.close()`** they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when using single-phase initialization or (static) global variables. It is possible to insert objects created in one sub-interpreter into a namespace of another (sub-)interpreter; this should be avoided if possible.

Special care should be taken to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. It is equally important to avoid sharing objects from which the above are reachable.

Also note that combining this functionality with `PyGILState_*` APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don't switch sub-interpreters between a pair of matching

`PyGILState_Ensure()` and `PyGILState_Release()` calls. Furthermore, extensions (such as `ctypes`) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.

Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

int Py_AddPendingCall(int (*func)(void*), void *arg)

Part of the Stable ABI.
Schedule a function to be called from the main interpreter thread. On success, `0` is returned and *func* is queued for being called in the main thread. On failure, `-1` is returned without setting any exception.

When successfully queued, *func* will be *eventually* called from the main interpreter thread with the argument *arg*. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a bytecode boundary;
- with the main thread holding the global interpreter lock (*func* can therefore use the full C API).

func must return `0` on success, or `-1` on failure with an exception set. *func* won't be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released.

This function doesn't need a current thread state to run, and it doesn't need the global interpreter lock.

To call this function in a subinterpreter, the caller must hold the GIL. Otherwise, the function *func* can be scheduled to be called from the wrong interpreter.

Warning

This is a low-level function, only useful for very special cases. There is no guarantee that *func* will be called as quick as possible. If the main thread is busy executing a system call, *func* won't be called before the system call returns. This function is generally **not** suitable for calling Python code from arbitrary C threads. Instead, use the PyGILState API.

Changed in version 3.9: If this function is called in a subinterpreter, the function *func* is now scheduled to be called from the subinterpreter, rather than being called from the main interpreter. Each subinterpreter now has its own list of scheduled calls.

New in version 3.1.

Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

typedef int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)

The type of the trace function registered using **`PyEval_SetProfile()`** and **`PyEval_SetTrace()`**. The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants **`PyTrace_CALL`**, **`PyTrace_EXCEPTION`**, **`PyTrace_LINE`**,

PyTrace_RETURN, **PyTrace_C_CALL**, **PyTrace_C_EXCEPTION**, **PyTrace_C_RETURN**, or **PyTrace_OPCODE**, and *arg* depends on the value of *what*:

Value of *what*	Meaning of *arg*
PyTrace_CALL	Always **Py_None**.
PyTrace_EXCEPTION	Exception information as returned by **sys.exc_info()**.
PyTrace_LINE	Always **Py_None**.
PyTrace_RETURN	Value being returned to the caller, or `NULL` if caused by an exception.
PyTrace_C_CALL	Function object being called.
PyTrace_C_EXCEPTION	Function object being called.
PyTrace_C_RETURN	Function object being called.
PyTrace_OPCODE	Always **Py_None**.

int PyTrace_CALL

The value of the *what* parameter to a **Py_tracefunc** function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

int PyTrace_EXCEPTION

The value of the *what* parameter to a **Py_tracefunc** function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

int PyTrace_LINE

The value passed as the *what* parameter to a **Py_tracefunc** function (but not a profiling function) when a line-number event is being reported. It may be disabled for a frame by setting **f_trace_lines** to *0* on that frame.

int PyTrace_RETURN

The value for the *what* parameter to **Py_tracefunc** functions when a call is about to return.

int PyTrace_C_CALL

The value for the *what* parameter to **Py_tracefunc** functions when a C function is about to be called.

int PyTrace_C_EXCEPTION

The value for the *what* parameter to **Py_tracefunc** functions when a C function has raised an exception.

int PyTrace_C_RETURN

The value for the *what* parameter to **Py_tracefunc** functions when a C function has returned.

int PyTrace_OPCODE

The value for the *what* parameter to **Py_tracefunc** functions (but not profiling functions) when a new opcode is about to be executed. This event is not emitted by default: it must be explicitly requested by setting **f_trace_opcodes** to *1* on the frame.

void PyEval_SetProfile(Py_tracefunc func, PyObject *obj)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except **PyTrace_LINE** **PyTrace_OPCODE** and **PyTrace_EXCEPTION**.

See also the **sys.setprofile()** function.

The caller must hold the GIL.

void PyEval_SetTrace(Py_tracefunc func, PyObject *obj)

Set the tracing function to *func*. This is similar to **PyEval_SetProfile()**, except the tracing function does receive line-number events and per-opcode events, but does not receive any event related to C function objects being called. Any trace function registered using **PyEval_SetTrace()** will not receive **PyTrace_C_CALL**, **PyTrace_C_EXCEPTION** or **PyTrace_C_RETURN** as a value for the *what* parameter.

See also the **sys.settrace()** function.

The caller must hold the GIL.

Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

PyInterpreterState *PyInterpreterState_Head()

Return the interpreter state object at the head of the list of all such objects.

PyInterpreterState *PyInterpreterState_Main()

Return the main interpreter state object.

PyInterpreterState *PyInterpreterState_Next(PyInterpreterState *interp)

Return the next interpreter state object after *interp* from the list of all such objects.

PyThreadState *PyInterpreterState_ThreadHead(PyInterpreterState *interp)

Return the pointer to the first **PyThreadState** object in the list of threads associated with the interpreter *interp*.

PyThreadState *PyThreadState_Next(PyThreadState *tstate)

Return the next thread state object after *tstate* from the list of

all such objects belonging to the same **PyInterpreterState** object.

Thread Local Storage Support

The Python interpreter provides low-level support for thread-local storage (TLS) which wraps the underlying native TLS implementation to support the Python-level thread local storage API (**threading.local**). The CPython C level APIs are similar to those offered by pthreads and Windows: use a thread key and functions to associate a void* value per thread.

The GIL does *not* need to be held when calling these functions; they supply their own locking.

Note that `Python.h` does not include the declaration of the TLS APIs, you need to include `pythread.h` to use thread-local storage.

Note

None of these API functions handle memory management on behalf of the void* values. You need to allocate and deallocate them yourself. If the void* values happen to be PyObject*, these functions don't do refcount operations on them either.

Thread Specific Storage (TSS) API

TSS API is introduced to supersede the use of the existing TLS API within the CPython interpreter. This API uses a new type **Py_tss_t** instead of int to represent thread keys.

New in version 3.7.

See also

"A New C-API for Thread-Local Storage in CPython" (**PEP 539** [https://peps.python.org/pep-0539/])

type Py_tss_t

This data structure represents the state of a thread key, the definition of which may depend on the underlying TLS implementation, and it has an internal field representing the key's initialization state. There are no public members in this structure.

When Py_LIMITED_API is not defined, static allocation of this type by **Py_tss_NEEDS_INIT** is allowed.

Py_tss_NEEDS_INIT

This macro expands to the initializer for **Py_tss_t** variables. Note that this macro won't be defined with Py_LIMITED_API.

Dynamic Allocation

Dynamic allocation of the **Py_tss_t**, required in extension modules built with Py_LIMITED_API, where static allocation of this type is not possible due to its implementation being opaque at build time.

Py_tss_t *PyThread_tss_alloc()

Part of the Stable ABI since version 3.7.
Return a value which is the same state as a value initialized with **Py_tss_NEEDS_INIT**, or `NULL` in the case of dynamic allocation failure.

void PyThread_tss_free(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Free the given *key* allocated by **PyThread_tss_alloc()**, after first calling **PyThread_tss_delete()** to ensure any associated thread locals have been unassigned. This is a no-op if the *key* argument is `NULL`.

Note

A freed key becomes a dangling pointer. You should reset the key to `NULL`.

Methods

The parameter *key* of these functions must not be `NULL`. Moreover, the behaviors of **`PyThread_tss_set()`** and **`PyThread_tss_get()`** are undefined if the given **`Py_tss_t`** has not been initialized by **`PyThread_tss_create()`**.

int PyThread_tss_is_created(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return a non-zero value if the given **`Py_tss_t`** has been initialized by **`PyThread_tss_create()`**.

int PyThread_tss_create(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return a zero value on successful initialization of a TSS key. The behavior is undefined if the value pointed to by the *key* argument is not initialized by **`Py_tss_NEEDS_INIT`**. This function can be called repeatedly on the same key – calling it on an already initialized key is a no-op and immediately returns success.

void PyThread_tss_delete(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Destroy a TSS key to forget the values associated with the key across all threads, and change the key's initialization state to uninitialized. A destroyed key is able to be initialized again by **`PyThread_tss_create()`**. This function can be called repeatedly on the same key – calling it on an already destroyed key is a no-op.

int PyThread_tss_set(Py_tss_t *key, void *value)

Part of the Stable ABI since version 3.7.
Return a zero value to indicate successfully associating a void* value with a TSS key in the current thread. Each thread has a distinct mapping of the key to a void* value.

void *PyThread_tss_get(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return the void* value associated with a TSS key in the current thread. This returns `NULL` if no value is associated with the key in the current thread.

Thread Local Storage (TLS) API

Deprecated since version 3.7: This API is superseded by Thread Specific Storage (TSS) API.

Note

This version of the API does not support platforms where the native TLS key is defined in a way that cannot be safely cast to `int`. On such platforms, **`PyThread_create_key()`** will return immediately with a failure status, and the other TLS functions will all be no-ops on such platforms.

Due to the compatibility problem noted above, this version of the API should not be used in new code.

int PyThread_create_key()

Part of the Stable ABI.

void PyThread_delete_key(int key)

Part of the Stable ABI.

int PyThread_set_key_value(int key, void *value)

Part of the Stable ABI.

void *PyThread_get_key_value(int key)

Part of the Stable ABI.

void PyThread_delete_key_value(int key)

Part of the Stable ABI.

void PyThread_ReInitTLS()

Part of the Stable ABI.

Python Initialization Configuration

New in version 3.8.

Python can be initialized with `Py_InitializeFromConfig()` and the `PyConfig` structure. It can be preinitialized with `Py_PreInitialize()` and the `PyPreConfig` structure.

There are two kinds of configuration:

- The Python Configuration can be used to build a customized Python which behaves as the regular Python. For example, environment variables and command line arguments are used to configure Python.
- The Isolated Configuration can be used to embed Python into an application. It isolates Python from the system. For example, environment variables are ignored, the LC_CTYPE locale is left unchanged and no signal handler is registered.

The `Py_RunMain()` function can be used to write a customized Python program.

See also Initialization, Finalization, and Threads.

See also

PEP 587 [https://peps.python.org/pep-0587/] "Python Initialization Configuration".

Example

Example of customized Python always running in isolated mode:

```
int main(int argc, char **argv)
```

```
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config.isolated = 1;

    /* Decode command line arguments.
       Implicitly preinitialize Python (in isolated mode
    status = PyConfig_SetBytesArgv(&config, argc, argv);
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);

    return Py_RunMain();

exception:
    PyConfig_Clear(&config);
    if (PyStatus_IsExit(status)) {
        return status.exitcode;
    }
    /* Display the error message and exit the process wi
       non-zero exit code */
    Py_ExitStatusException(status);
}
```

PyWideStringList

type PyWideStringList

List of `wchar_t*` strings.

If *length* is non-zero, *items* must be non-`NULL` and all strings

must be non-`NULL`.

Methods:

PyStatus PyWideStringList_Append(PyWideStringList *list, const wchar_t *item)

Append *item* to *list*.

Python must be preinitialized to call this function.

PyStatus PyWideStringList_Insert(PyWideStringList *list, Py_ssize_t index, const wchar_t *item)

Insert *item* into *list* at *index*.

If *index* is greater than or equal to *list* length, append *item* to *list*.

index must be greater than or equal to `0`.

Python must be preinitialized to call this function.

Structure fields:

Py_ssize_t length

List length.

wchar_t **items

List items.

PyStatus

type PyStatus

Structure to store an initialization function status: success, error or exit.

For an error, it can store the C function name which created the error.

Structure fields:

int exitcode
: Exit code. Argument passed to `exit()`.

const char *err_msg
: Error message.

const char *func
: Name of the function which created an error, can be `NULL`.

Functions to create a status:

PyStatus PyStatus_Ok(void)
: Success.

PyStatus PyStatus_Error(const char *err_msg)
: Initialization error with a message.

  err_msg must not be `NULL`.

PyStatus PyStatus_NoMemory(void)
: Memory allocation failure (out of memory).

PyStatus PyStatus_Exit(int exitcode)
: Exit Python with the specified exit code.

Functions to handle a status:

int PyStatus_Exception(PyStatus status)
: Is the status an error or an exit? If true, the exception must be handled; by calling **`Py_ExitStatusException()`** for example.

int PyStatus_IsError(PyStatus status)

Is the result an error?

int PyStatus_IsExit(PyStatus status)

Is the result an exit?

void Py_ExitStatusException(PyStatus status)

Call `exit(exitcode)` if *status* is an exit. Print the error message and exit with a non-zero exit code if *status* is an error. Must only be called if `PyStatus_Exception(status)` is non-zero.

Note

Internally, Python uses macros which set `PyStatus.func`, whereas functions to create a status set `func` to `NULL`.

Example:

```
PyStatus alloc(void **ptr, size_t size)
{
    *ptr = PyMem_RawMalloc(size);
    if (*ptr == NULL) {
        return PyStatus_NoMemory();
    }
    return PyStatus_Ok();
}

int main(int argc, char **argv)
{
    void *ptr;
    PyStatus status = alloc(&ptr, 16);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }
    PyMem_Free(ptr);
    return 0;
}
```

PyPreConfig

type PyPreConfig

Structure used to preinitialize Python.

Function to initialize a preconfiguration:

void PyPreConfig_InitPythonConfig(PyPreConfig *preconfig)

Initialize the preconfiguration with Python Configuration.

void PyPreConfig_InitIsolatedConfig(PyPreConfig *preconfig)

Initialize the preconfiguration with Isolated Configuration.

Structure fields:

int allocator

Name of the Python memory allocators:

- `PYMEM_ALLOCATOR_NOT_SET` (`0`): don't change memory allocators (use defaults).
- `PYMEM_ALLOCATOR_DEFAULT` (`1`): default memory allocators.
- `PYMEM_ALLOCATOR_DEBUG` (`2`): default memory allocators with debug hooks.
- `PYMEM_ALLOCATOR_MALLOC` (`3`): use `malloc()` of the C library.
- `PYMEM_ALLOCATOR_MALLOC_DEBUG` (`4`): force usage of `malloc()` with debug hooks.
- `PYMEM_ALLOCATOR_PYMALLOC` (`5`): Python pymalloc memory allocator.
- `PYMEM_ALLOCATOR_PYMALLOC_DEBUG` (`6`): Python pymalloc memory allocator with debug hooks.

`PYMEM_ALLOCATOR_PYMALLOC` and `PYMEM_ALLOCATOR_PYMALLOC_DEBUG` are not supported if Python is **`configured using --`**

without-pymalloc.

See Memory Management.

Default: `PYMEM_ALLOCATOR_NOT_SET`.

int configure_locale
: Set the LC_CTYPE locale to the user preferred locale.

  If equals to `0`, set **coerce_c_locale** and **coerce_c_locale_warn** members to `0`.

  See the locale encoding.

  Default: `1` in Python config, `0` in isolated config.

int coerce_c_locale
: If equals to `2`, coerce the C locale.

  If equals to `1`, read the LC_CTYPE locale to decide if it should be coerced.

  See the locale encoding.

  Default: `-1` in Python config, `0` in isolated config.

int coerce_c_locale_warn
: If non-zero, emit a warning if the C locale is coerced.

  Default: `-1` in Python config, `0` in isolated config.

int dev_mode
: Python Development Mode: see **PyConfig.dev_mode**.

  Default: `-1` in Python mode, `0` in isolated mode.

int isolated
: Isolated mode: see **PyConfig.isolated**.

Default: `0` in Python mode, `1` in isolated mode.

int legacy_windows_fs_encoding

If non-zero:

- Set **`PyPreConfig.utf8_mode`** to `0`,
- Set **`PyConfig.filesystem_encoding`** to `"mbcs"`,
- Set **`PyConfig.filesystem_errors`** to `"replace"`.

Initialized the from **`PYTHONLEGACYWINDOWSFSENCODING`** environment variable value.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: `0`.

int parse_argv

If non-zero, **`Py_PreInitializeFromArgs()`** and **`Py_PreInitializeFromBytesArgs()`** parse their `argv` argument the same way the regular Python parses command line arguments: see Command Line Arguments.

Default: `1` in Python config, `0` in isolated config.

int use_environment

Use environment variables? See **`PyConfig.use_environment`**.

Default: `1` in Python config and `0` in isolated config.

int utf8_mode

If non-zero, enable the Python UTF-8 Mode.

Set to `0` or `1` by the **`-X utf8`** command line option and the **`PYTHONUTF8`** environment variable.

Also set to `1` if the `LC_CTYPE` locale is `C` or `POSIX`.

Default: `-1` in Python config and `0` in isolated config.

Preinitialize Python with PyPreConfig

The preinitialization of Python:

- Set the Python memory allocators (**`PyPreConfig.allocator`**)
- Configure the LC_CTYPE locale (locale encoding)
- Set the Python UTF-8 Mode (**`PyPreConfig.utf8_mode`**)

The current preconfiguration (`PyPreConfig` type) is stored in `_PyRuntime.preconfig`.

Functions to preinitialize Python:

PyStatus Py_PreInitialize(const PyPreConfig *preconfig)

Preinitialize Python from *preconfig* preconfiguration.

preconfig must not be `NULL`.

PyStatus Py_PreInitializeFromBytesArgs(const PyPreConfig *preconfig, int argc, char *const *argv)

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (bytes strings) if **`parse_argv`** of *preconfig* is non-zero.

preconfig must not be `NULL`.

PyStatus Py_PreInitializeFromArgs(const PyPreConfig *preconfig, int argc, wchar_t *const *argv)

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (wide strings) if **`parse_argv`** of *preconfig* is non-zero.

preconfig must not be `NULL`.

The caller is responsible to handle exceptions (error or exit) using **`PyStatus_Exception()`** and **`Py_ExitStatusException()`**.

For Python Configuration (**`PyPreConfig_InitPythonConfig()`**), if Python is initialized with command line arguments, the command line arguments must also be passed to preinitialize Python, since they have an effect on the pre-configuration like encodings. For example, the **`-X utf8`** command line option enables the Python UTF-8 Mode.

`PyMem_SetAllocator()` can be called after **`Py_PreInitialize()`** and before **`Py_InitializeFromConfig()`** to install a custom memory allocator. It can be called before **`Py_PreInitialize()`** if **`PyPreConfig.allocator`** is set to `PYMEM_ALLOCATOR_NOT_SET`.

Python memory allocation functions like **`PyMem_RawMalloc()`** must not be used before the Python preinitialization, whereas calling directly `malloc()` and `free()` is always safe. **`Py_DecodeLocale()`** must not be called before the Python preinitialization.

Example using the preinitialization to enable the Python UTF-8 Mode:

```
PyStatus status;
PyPreConfig preconfig;
PyPreConfig_InitPythonConfig(&preconfig);

preconfig.utf8_mode = 1;

status = Py_PreInitialize(&preconfig);
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}

/* at this point, Python speaks UTF-8 */
```

```
Py_Initialize();
/* ... use Python API here ... */
Py_Finalize();
```

PyConfig

type PyConfig

Structure containing most parameters to configure Python.

When done, the **`PyConfig_Clear()`** function must be used to release the configuration memory.

Structure methods:

void PyConfig_InitPythonConfig(PyConfig *config)

Initialize configuration with the Python Configuration.

void PyConfig_InitIsolatedConfig(PyConfig *config)

Initialize configuration with the Isolated Configuration.

PyStatus PyConfig_SetString(PyConfig *config, wchar_t *const *config_str, const wchar_t *str)

Copy the wide character string *str* into `*config_str`.

Preinitialize Python if needed.

PyStatus PyConfig_SetBytesString(PyConfig *config, wchar_t *const *config_str, const char *str)

Decode *str* using **`Py_DecodeLocale()`** and set the result into `*config_str`.

Preinitialize Python if needed.

PyStatus PyConfig_SetArgv(PyConfig *config, int argc, wchar_t *const *argv)

Set command line arguments (**`argv`** member of *config*)

from the *argv* list of wide character strings.

Preinitialize Python if needed.

PyStatus PyConfig_SetBytesArgv(PyConfig *config, int argc, char *const *argv)

Set command line arguments (**argv** member of *config*) from the *argv* list of bytes strings. Decode bytes using **Py_DecodeLocale()**.

Preinitialize Python if needed.

PyStatus PyConfig_SetWideStringList(PyConfig *config, PyWideStringList *list, Py_ssize_t length, wchar_t **items)

Set the list of wide strings *list* to *length* and *items*.

Preinitialize Python if needed.

PyStatus PyConfig_Read(PyConfig *config)

Read all Python configuration.

Fields which are already initialized are left unchanged.

Fields for path configuration are no longer calculated or modified when calling this function, as of Python 3.11.

The **PyConfig_Read()** function only parses **PyConfig.argv** arguments once: **PyConfig.parse_argv** is set to `2` after arguments are parsed. Since Python arguments are strippped from **PyConfig.argv**, parsing arguments twice would parse the application options as Python options.

Preinitialize Python if needed.

Changed in version 3.10: The **PyConfig.argv** arguments are now only parsed once, **PyConfig.parse_argv** is set to `2` after arguments are parsed, and arguments are only parsed if

PyConfig.parse_argv equals `1`.

Changed in version 3.11: **PyConfig_Read()** no longer calculates all paths, and so fields listed under Python Path Configuration may no longer be updated until **Py_InitializeFromConfig()** is called.

void PyConfig_Clear(PyConfig *config)

Release configuration memory.

Most `PyConfig` methods preinitialize Python if needed. In that case, the Python preinitialization configuration (**PyPreConfig**) in based on the **PyConfig**. If configuration fields which are in common with **PyPreConfig** are tuned, they must be set before calling a **PyConfig** method:

- **PyConfig.dev_mode**
- **PyConfig.isolated**
- **PyConfig.parse_argv**
- **PyConfig.use_environment**

Moreover, if **PyConfig_SetArgv()** or **PyConfig_SetBytesArgv()** is used, this method must be called before other methods, since the preinitialization configuration depends on command line arguments (if **parse_argv** is non-zero).

The caller of these methods is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

Structure fields:

PyWideStringList argv

Command line arguments: **sys.argv**.

Set **parse_argv** to `1` to parse **argv** the same way the regular Python parses Python command line arguments and then to strip Python arguments from **argv**.

If **argv** is empty, an empty string is added to ensure that **sys.argv** always exists and is never empty.

Default: NULL.

See also the **orig_argv** member.

int safe_path

If equals to zero, Py_RunMain() prepends a potentially unsafe path to **sys.path** at startup:

- If **argv[0]** is equal to L"-m" (python -m module), prepend the current working directory.
- If running a script (python script.py), prepend the script's directory. If it's a symbolic link, resolve symbolic links.
- Otherwise (python -c code and python), prepend an empty string, which means the current working directory.

Set to 1 by the **-P** command line option and the **PYTHONSAFEPATH** environment variable.

Default: 0 in Python config, 1 in isolated config.

New in version 3.11.

wchar_t *base_exec_prefix

sys.base_exec_prefix.

Default: NULL.

Part of the Python Path Configuration output.

wchar_t *base_executable

Python base executable: **sys._base_executable**.

Set by the **__PYVENV_LAUNCHER__** environment variable.

Set from **PyConfig.executable** if NULL.

Default: `NULL`.

Part of the Python Path Configuration output.

wchar_t *base_prefix

`sys.base_prefix`.

Default: `NULL`.

Part of the Python Path Configuration output.

int buffered_stdio

If equals to `0` and **`configure_c_stdio`** is non-zero, disable buffering on the C streams stdout and stderr.

Set to `0` by the **`-u`** command line option and the **`PYTHONUNBUFFERED`** environment variable.

stdin is always opened in buffered mode.

Default: `1`.

int bytes_warning

If equals to `1`, issue a warning when comparing **`bytes`** or **`bytearray`** with **`str`**, or comparing **`bytes`** with **`int`**.

If equal or greater to `2`, raise a **`BytesWarning`** exception in these cases.

Incremented by the **`-b`** command line option.

Default: `0`.

int warn_default_encoding

If non-zero, emit a **`EncodingWarning`** warning when **`io.TextIOWrapper`** uses its default encoding. See Opt-in EncodingWarning for details.

Default: `0`.

New in version 3.10.

int code_debug_ranges

If equals to `0`, disables the inclusion of the end line and column mappings in code objects. Also disables traceback printing carets to specific error locations.

Set to `0` by the **PYTHONNODEBUGRANGES** environment variable and by the **-X no_debug_ranges** command line option.

Default: `1`.

New in version 3.11.

wchar_t *check_hash_pycs_mode

Control the validation behavior of hash-based `.pyc` files: value of the **--check-hash-based-pycs** command line option.

Valid values:

- `L"always"`: Hash the source file for invalidation regardless of value of the 'check_source' flag.
- `L"never"`: Assume that hash-based pycs always are valid.
- `L"default"`: The 'check_source' flag in hash-based pycs determines invalidation.

Default: `L"default"`.

See also **PEP 552** [https://peps.python.org/pep-0552/] "Deterministic pycs".

int configure_c_stdio

If non-zero, configure C standard streams:

- On Windows, set the binary mode (`O_BINARY`) on stdin, stdout and stderr.
- If **buffered_stdio** equals zero, disable

buffering of stdin, stdout and stderr streams.
- If **interactive** is non-zero, enable stream buffering on stdin and stdout (only stdout on Windows).

Default: `1` in Python config, `0` in isolated config.

int dev_mode

If non-zero, enable the Python Development Mode.

Set to `1` by the **-X dev** option and the **PYTHONDEVMODE** environment variable.

Default: `-1` in Python mode, `0` in isolated mode.

int dump_refs

Dump Python references?

If non-zero, dump all objects which are still alive at exit.

Set to `1` by the **PYTHONDUMPREFS** environment variable.

Need a special build of Python with the `Py_TRACE_REFS` macro defined: see the **configure --with-trace-refs option**.

Default: `0`.

wchar_t *exec_prefix

The site-specific directory prefix where the platform-dependent Python files are installed: **sys.exec_prefix**.

Default: `NULL`.

Part of the Python Path Configuration output.

wchar_t *executable

The absolute path of the executable binary for the Python interpreter: **`sys.executable`**.

Default: `NULL`.

Part of the Python Path Configuration output.

int faulthandler

Enable faulthandler?

If non-zero, call **`faulthandler.enable()`** at startup.

Set to `1` by **`-X faulthandler`** and the **`PYTHONFAULTHANDLER`** environment variable.

Default: `-1` in Python mode, `0` in isolated mode.

wchar_t *filesystem_encoding

Filesystem encoding: **`sys.getfilesystemencoding()`**.

On macOS, Android and VxWorks: use `"utf-8"` by default.

On Windows: use `"utf-8"` by default, or `"mbcs"` if **`legacy_windows_fs_encoding`** of **`PyPreConfig`** is non-zero.

Default encoding on other platforms:

- `"utf-8"` if **`PyPreConfig.utf8_mode`** is non-zero.
- `"ascii"` if Python detects that `nl_langinfo(CODESET)` announces the ASCII encoding, whereas the `mbstowcs()` function decodes from a different encoding (usually Latin1).
- `"utf-8"` if `nl_langinfo(CODESET)` returns an empty string.
- Otherwise, use the locale encoding:

`nl_langinfo(CODESET)` result.

At Python startup, the encoding name is normalized to the Python codec name. For example, `"ANSI_X3.4-1968"` is replaced with `"ascii"`.

See also the **`filesystem_errors`** member.

wchar_t *filesystem_errors

Filesystem error handler: **`sys.getfilesystemencodeerrors()`**.

On Windows: use `"surrogatepass"` by default, or `"replace"` if **`legacy_windows_fs_encoding`** of **`PyPreConfig`** is non-zero.

On other platforms: use `"surrogateescape"` by default.

Supported error handlers:

- `"strict"`
- `"surrogateescape"`
- `"surrogatepass"` (only supported with the UTF-8 encoding)

See also the **`filesystem_encoding`** member.

unsigned long hash_seed

int use_hash_seed

Randomized hash function seed.

If **`use_hash_seed`** is zero, a seed is chosen randomly at Python startup, and **`hash_seed`** is ignored.

Set by the **`PYTHONHASHSEED`** environment variable.

Default *use_hash_seed* value: `-1` in Python mode, `0` in isolated mode.

wchar_t *home

Python home directory.

If **Py_SetPythonHome()** has been called, use its argument if it is not NULL.

Set by the **PYTHONHOME** environment variable.

Default: NULL.

Part of the Python Path Configuration input.

int import_time

If non-zero, profile import time.

Set the 1 by the **-X importtime** option and the **PYTHONPROFILEIMPORTTIME** environment variable.

Default: 0.

int inspect

Enter interactive mode after executing a script or a command.

If greater than 0, enable inspect: when a script is passed as first argument or the -c option is used, enter interactive mode after executing the script or the command, even when **sys.stdin** does not appear to be a terminal.

Incremented by the **-i** command line option. Set to 1 if the **PYTHONINSPECT** environment variable is non-empty.

Default: 0.

int install_signal_handlers

Install Python signal handlers?

Default: 1 in Python mode, 0 in isolated mode.

int interactive

If greater than `0`, enable the interactive mode (REPL).

Incremented by the **`-i`** command line option.

Default: `0`.

int isolated

If greater than `0`, enable isolated mode:

- Set **`safe_path`** to `1`: don't prepend a potentially unsafe path to **`sys.path`** at Python startup.
- Set **`use_environment`** to `0`.
- Set **`user_site_directory`** to `0`: don't add the user site directory to **`sys.path`**.
- Python REPL doesn't import **`readline`** nor enable default readline configuration on interactive prompts.

Set to `1` by the **`-I`** command line option.

Default: `0` in Python mode, `1` in isolated mode.

See also **`PyPreConfig.isolated`**.

int legacy_windows_stdio

If non-zero, use **`io.FileIO`** instead of **`io.WindowsConsoleIO`** for **`sys.stdin`**, **`sys.stdout`** and **`sys.stderr`**.

Set to `1` if the **`PYTHONLEGACYWINDOWSSTDIO`** environment variable is set to a non-empty string.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: `0`.

See also the **PEP 528** [https://peps.python.org/pep-0528/] (Change Windows console encoding to UTF-8).

int malloc_stats

If non-zero, dump statistics on Python pymalloc memory allocator at exit.

Set to `1` by the **`PYTHONMALLOCSTATS`** environment variable.

The option is ignored if Python is **`configured using the --without-pymalloc option`**.

Default: `0`.

wchar_t *platlibdir

Platform library directory name: **`sys.platlibdir`**.

Set by the **`PYTHONPLATLIBDIR`** environment variable.

Default: value of the `PLATLIBDIR` macro which is set by the **`configure --with-platlibdir option`** (default: `"lib"`, or `"DLLs"` on Windows).

Part of the Python Path Configuration input.

New in version 3.9.

Changed in version 3.11: This macro is now used on Windows to locate the standard library extension modules, typically under `DLLs`. However, for compatibility, note that this value is ignored for any non-standard layouts, including in-tree builds and virtual environments.

wchar_t *pythonpath_env

Module search paths (**`sys.path`**) as a string separated by `DELIM` (**`os.path.pathsep`**).

Set by the **`PYTHONPATH`** environment variable.

Default: `NULL`.

Part of the Python Path Configuration input.

PyWideStringList module_search_paths

int module_search_paths_set
: Module search paths: **sys.path**.

  If **module_search_paths_set** is equal to 0, **Py_InitializeFromConfig()** will replace **module_search_paths** and sets **module_search_paths_set** to 1.

  Default: empty list (module_search_paths) and 0 (module_search_paths_set).

  Part of the Python Path Configuration output.

int optimization_level
: Compilation optimization level:

  - 0: Peephole optimizer, set __debug__ to True.
  - 1: Level 0, remove assertions, set __debug__ to False.
  - 2: Level 1, strip docstrings.

  Incremented by the **-O** command line option. Set to the **PYTHONOPTIMIZE** environment variable value.

  Default: 0.

PyWideStringList orig_argv
: The list of the original command line arguments passed to the Python executable: **sys.orig_argv**.

  If **orig_argv** list is empty and **argv** is not a list only containing an empty string, **PyConfig_Read()** copies **argv** into **orig_argv** before modifying **argv** (if **parse_argv** is non-zero).

  See also the **argv** member and the **Py_GetArgcArgv()** function.

Default: empty list.

New in version 3.10.

int parse_argv

Parse command line arguments?

If equals to `1`, parse **`argv`** the same way the regular Python parses command line arguments, and strip Python arguments from **`argv`**.

The **`PyConfig_Read()`** function only parses **`PyConfig.argv`** arguments once: **`PyConfig.parse_argv`** is set to `2` after arguments are parsed. Since Python arguments are strippped from **`PyConfig.argv`**, parsing arguments twice would parse the application options as Python options.

Default: `1` in Python mode, `0` in isolated mode.

Changed in version 3.10: The **`PyConfig.argv`** arguments are now only parsed if **`PyConfig.parse_argv`** equals to `1`.

int parser_debug

Parser debug mode. If greater than `0`, turn on parser debugging output (for expert only, depending on compilation options).

Incremented by the **`-d`** command line option. Set to the **`PYTHONDEBUG`** environment variable value.

Default: `0`.

int pathconfig_warnings

If non-zero, calculation of path configuration is allowed to log warnings into `stderr`. If equals to `0`, suppress these warnings.

Default: `1` in Python mode, `0` in isolated mode.

Part of the Python Path Configuration input.

Changed in version 3.11: Now also applies on Windows.

wchar_t *prefix

The site-specific directory prefix where the platform independent Python files are installed: **sys.prefix**.

Default: NULL.

Part of the Python Path Configuration output.

wchar_t *program_name

Program name used to initialize **executable** and in early error messages during Python initialization.

- If **Py_SetProgramName()** has been called, use its argument.
- On macOS, use **PYTHONEXECUTABLE** environment variable if set.
- If the WITH_NEXT_FRAMEWORK macro is defined, use **__PYVENV_LAUNCHER__** environment variable if set.
- Use argv[0] of **argv** if available and non-empty.
- Otherwise, use L"python" on Windows, or L"python3" on other platforms.

Default: NULL.

Part of the Python Path Configuration input.

wchar_t *pycache_prefix

Directory where cached .pyc files are written: **sys.pycache_prefix**.

Set by the **-X pycache_prefix=PATH** command line option and the **PYTHONPYCACHEPREFIX** environment variable.

If `NULL`, **`sys.pycache_prefix`** is set to `None`.

Default: `NULL`.

int quiet

Quiet mode. If greater than `0`, don't display the copyright and version at Python startup in interactive mode.

Incremented by the **`-q`** command line option.

Default: `0`.

wchar_t *run_command

Value of the **`-c`** command line option.

Used by **`Py_RunMain()`**.

Default: `NULL`.

wchar_t *run_filename

Filename passed on the command line: trailing command line argument without **`-c`** or **`-m`**. It is used by the **`Py_RunMain()`** function.

For example, it is set to `script.py` by the `python3 script.py arg` command line.

See also the **`PyConfig.skip_source_first_line`** option.

Default: `NULL`.

wchar_t *run_module

Value of the **`-m`** command line option.

Used by **`Py_RunMain()`**.

Default: `NULL`.

int show_ref_count

Show total reference count at exit?

Set to `1` by **`-X showrefcount`** command line option.

Need a debug build of Python (the `Py_REF_DEBUG` macro must be defined).

Default: `0`.

int site_import

Import the **`site`** module at startup?

If equal to zero, disable the import of the module site and the site-dependent manipulations of **`sys.path`** that it entails.

Also disable these manipulations if the **`site`** module is explicitly imported later (call **`site.main()`** if you want them to be triggered).

Set to `0` by the **`-S`** command line option.

`sys.flags.no_site` is set to the inverted value of **`site_import`**.

Default: `1`.

int skip_source_first_line

If non-zero, skip the first line of the **`PyConfig.run_filename`** source.

It allows the usage of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Set to `1` by the **`-x`** command line option.

Default: `0`.

wchar_t *stdio_encoding

wchar_t *stdio_errors

Encoding and encoding errors of **sys.stdin**, **sys.stdout** and **sys.stderr** (but **sys.stderr** always uses "backslashreplace" error handler).

If **Py_SetStandardStreamEncoding()** has been called, use its *error* and *errors* arguments if they are not NULL.

Use the **PYTHONIOENCODING** environment variable if it is non-empty.

Default encoding:

- "UTF-8" if **PyPreConfig.utf8_mode** is non-zero.
- Otherwise, use the locale encoding.

Default error handler:

- On Windows: use "surrogateescape".
- "surrogateescape" if **PyPreConfig.utf8_mode** is non-zero, or if the LC_CTYPE locale is "C" or "POSIX".
- "strict" otherwise.

int tracemalloc

Enable tracemalloc?

If non-zero, call **tracemalloc.start()** at startup.

Set by **-X tracemalloc=N** command line option and by the **PYTHONTRACEMALLOC** environment variable.

Default: -1 in Python mode, 0 in isolated mode.

int use_environment

Use environment variables?

If equals to zero, ignore the environment variables.

Set to `0` by the **`-E`** environment variable.

Default: `1` in Python config and `0` in isolated config.

int user_site_directory

If non-zero, add the user site directory to **`sys.path`**.

Set to `0` by the **`-s`** and **`-I`** command line options.

Set to `0` by the **`PYTHONNOUSERSITE`** environment variable.

Default: `1` in Python mode, `0` in isolated mode.

int verbose

Verbose mode. If greater than `0`, print a message each time a module is imported, showing the place (filename or built-in module) from which it is loaded.

If greater or equal to `2`, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Incremented by the **`-v`** command line option.

Set to the **`PYTHONVERBOSE`** environment variable value.

Default: `0`.

PyWideStringList warnoptions

Options of the **`warnings`** module to build warnings filters, lowest to highest priority: **`sys.warnoptions`**.

The **`warnings`** module adds **`sys.warnoptions`** in the reverse order: the last **`PyConfig.warnoptions`** item becomes the first item of **`warnings.filters`** which is checked first (highest priority).

The **`-W`** command line options adds its value to **`warnoptions`**, it can be used multiple times.

The **PYTHONWARNINGS** environment variable can also be used to add warning options. Multiple options can be specified, separated by commas (`,`).

Default: empty list.

int write_bytecode

If equal to `0`, Python won't try to write `.pyc` files on the import of source modules.

Set to `0` by the **-B** command line option and the **PYTHONDONTWRITEBYTECODE** environment variable.

sys.dont_write_bytecode is initialized to the inverted value of **write_bytecode**.

Default: `1`.

PyWideStringList xoptions

Values of the **-X** command line options: **sys._xoptions**.

Default: empty list.

If **parse_argv** is non-zero, **argv** arguments are parsed the same way the regular Python parses command line arguments, and Python arguments are stripped from **argv**.

The **xoptions** options are parsed to set other options: see the **-X** command line option.

Changed in version 3.9: The `show_alloc_count` field has been removed.

Initialization with PyConfig

Function to initialize Python:

PyStatus Py_InitializeFromConfig(const PyConfig *config)

Initialize Python from *config* configuration.

The caller is responsible to handle exceptions (error or exit) using **`PyStatus_Exception()`** and **`Py_ExitStatusException()`**.

If **`PyImport_FrozenModules()`**, **`PyImport_AppendInittab()`** or **`PyImport_ExtendInittab()`** are used, they must be set or called after Python preinitialization and before the Python initialization. If Python is initialized multiple times, **`PyImport_AppendInittab()`** or **`PyImport_ExtendInittab()`** must be called before each Python initialization.

The current configuration (`PyConfig` type) is stored in `PyInterpreterState.config`.

Example setting the program name:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name. Implicitly preinitialize Py
    status = PyConfig_SetString(&config, &config.program
                                L"/path/to/my_program");
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);
    return;
```

```
exception:
    PyConfig_Clear(&config);
    Py_ExitStatusException(status);
}
```

More complete example modifying the default configuration, read the configuration, and then override some parameters. Note that since 3.11, many parameters are not calculated until initialization, and so values cannot be read from the configuration structure. Any values set before initialize is called will be left unchanged by initialization:

```
PyStatus init_python(const char *program_name)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name before reading the configura
       (decode byte string from the locale encoding).

       Implicitly preinitialize Python. */
    status = PyConfig_SetBytesString(&config, &config.pr
                                     program_name);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Read all configuration at once */
    status = PyConfig_Read(&config);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Specify sys.path explicitly */
    /* If you want to modify the default set of paths, f
       initialization first and then use PySys_GetObject
    config.module_search_paths_set = 1;
```

```
    status = PyWideStringList_Append(&config.module_sear
                                     L"/path/to/stdlib");
    if (PyStatus_Exception(status)) {
        goto done;
    }
    status = PyWideStringList_Append(&config.module_sear
                                     L"/path/to/more/mod
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Override executable computed by PyConfig_Read() *
    status = PyConfig_SetString(&config, &config.executa
                                L"/path/to/my_executable
    if (PyStatus_Exception(status)) {
        goto done;
    }

    status = Py_InitializeFromConfig(&config);

done:
    PyConfig_Clear(&config);
    return status;
}
```

Isolated Configuration

`PyPreConfig_InitIsolatedConfig()` and **`PyConfig_InitIsolatedConfig()`** functions create a configuration to isolate Python from the system. For example, to embed Python into an application.

This configuration ignores global configuration variables, environment variables, command line arguments (**`PyConfig.argv`** is not parsed) and user site directory. The C standard streams (ex: `stdout`) and the LC_CTYPE locale are left unchanged. Signal handlers are not installed.

Configuration files are still used with this configuration to

determine paths that are unspecified. Ensure **PyConfig.home** is specified to avoid computing the default path configuration.

Python Configuration

PyPreConfig_InitPythonConfig() and **PyConfig_InitPythonConfig()** functions create a configuration to build a customized Python which behaves as the regular Python.

Environments variables and command line arguments are used to configure Python, whereas global configuration variables are ignored.

This function enables C locale coercion (**PEP 538** [https://peps.python.org/pep-0538/]) and Python UTF-8 Mode (**PEP 540** [https://peps.python.org/pep-0540/]) depending on the LC_CTYPE locale, **PYTHONUTF8** and **PYTHONCOERCECLOCALE** environment variables.

Python Path Configuration

PyConfig contains multiple fields for the path configuration:

- Path configuration inputs:
  - **PyConfig.home**
  - **PyConfig.platlibdir**
  - **PyConfig.pathconfig_warnings**
  - **PyConfig.program_name**
  - **PyConfig.pythonpath_env**
  - current working directory: to get absolute paths
  - `PATH` environment variable to get the program full path (from **PyConfig.program_name**)
  - `__PYVENV_LAUNCHER__` environment variable
  - (Windows only) Application paths in the registry under "SoftwarePythonPythonCoreX.YPythonPath" of HKEY_CURRENT_USER and HKEY_LOCAL_MACHINE (where X.Y is the Python version).
- Path configuration output fields:

- **PyConfig.base_exec_prefix**
- **PyConfig.base_executable**
- **PyConfig.base_prefix**
- **PyConfig.exec_prefix**
- **PyConfig.executable**
- **PyConfig.module_search_paths_set**, **PyConfig.module_search_paths**
- **PyConfig.prefix**

If at least one “output field” is not set, Python calculates the path configuration to fill unset fields. If **module_search_paths_set** is equal to `0`, **module_search_paths** is overridden and **module_search_paths_set** is set to `1`.

It is possible to completely ignore the function calculating the default path configuration by setting explicitly all path configuration output fields listed above. A string is considered as set even if it is non-empty. `module_search_paths` is considered as set if `module_search_paths_set` is set to `1`. In this case, `module_search_paths` will be used without modification.

Set **pathconfig_warnings** to `0` to suppress warnings when calculating the path configuration (Unix only, Windows does not log any warning).

If **base_prefix** or **base_exec_prefix** fields are not set, they inherit their value from **prefix** and **exec_prefix** respectively.

Py_RunMain() and **Py_Main()** modify **sys.path**:

- If **run_filename** is set and is a directory which contains a `__main__.py` script, prepend **run_filename** to **sys.path**.
- If **isolated** is zero:
  - If **run_module** is set, prepend the current directory to **sys.path**. Do nothing if the current directory cannot be read.
  - If **run_filename** is set, prepend the directory of the filename to **sys.path**.
  - Otherwise, prepend an empty string to **sys.path**.

If **site_import** is non-zero, **sys.path** can be modified by the **site** module. If **user_site_directory** is non-zero and the user's site-package directory exists, the **site** module appends the user's site-package directory to **sys.path**.

The following configuration files are used by the path configuration:

- pyvenv.cfg
- ._pth file (ex: python._pth)
- pybuilddir.txt (Unix only)

If a ._pth file is present:

- Set **isolated** to 1.
- Set **use_environment** to 0.
- Set **site_import** to 0.
- Set **safe_path** to 1.

The __PYVENV_LAUNCHER__ environment variable is used to set **PyConfig.base_executable**

Py_RunMain()

int Py_RunMain(void)

Execute the command (**PyConfig.run_command**), the script (**PyConfig.run_filename**) or the module (**PyConfig.run_module**) specified on the command line or in the configuration.

By default and when if **-i** option is used, run the REPL.

Finally, finalizes Python and returns an exit status that can be passed to the exit() function.

See Python Configuration for an example of customized Python always running in isolated mode using **Py_RunMain()**.

Py_GetArgcArgv()

void Py_GetArgcArgv(int *argc, wchar_t ***argv)

Get the original command line arguments, before Python modified them.

See also **PyConfig.orig_argv** member.

Multi-Phase Initialization Private Provisional API

This section is a private provisional API introducing multi-phase initialization, the core feature of **PEP 432** [https://peps.python.org/pep-0432/]:

- "Core" initialization phase, "bare minimum Python":
  - Builtin types;
  - Builtin exceptions;
  - Builtin and frozen modules;
  - The **sys** module is only partially initialized (ex: **sys.path** doesn't exist yet).
- "Main" initialization phase, Python is fully initialized:
  - Install and configure **importlib**;
  - Apply the Path Configuration;
  - Install signal handlers;
  - Finish **sys** module initialization (ex: create **sys.stdout** and **sys.path**);
  - Enable optional features like **faulthandler** and **tracemalloc**;
  - Import the **site** module;
  - etc.

Private provisional API:

- **PyConfig._init_main**: if set to `0`, **Py_InitializeFromConfig()** stops at the "Core" initialization phase.
- **PyConfig._isolated_interpreter**: if non-zero, disallow threads, subprocesses and fork.

PyStatus _Py_InitializeMain(void)

Move to the “Main” initialization phase, finish the Python initialization.

No module is imported during the “Core” phase and the `importlib` module is not configured: the Path Configuration is only applied during the “Main” phase. It may allow to customize Python in Python to override or tune the Path Configuration, maybe install a custom **`sys.meta_path`** importer or an import hook, etc.

It may become possible to calculatin the Path Configuration in Python, after the Core phase and before the Main phase, which is one of the **PEP 432** [https://peps.python.org/pep-0432/] motivation.

The “Core” phase is not properly defined: what should be and what should not be available at this phase is not specified yet. The API is marked as private and provisional: the API can be modified or even be removed anytime until a proper public API is designed.

Example running Python code between “Core” and “Main” initialization phases:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config._init_main = 0;

    /* ... customize 'config' configuration ... */

    status = Py_InitializeFromConfig(&config);
    PyConfig_Clear(&config);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }

    /* Use sys.stderr because sys.stdout is only created
       by _Py_InitializeMain() */
    int res = PyRun_SimpleString(
```

```
        "import sys; "
        "print('Run Python code before _Py_InitializeMai
               "file=sys.stderr)");
    if (res < 0) {
        exit(1);
    }

    /* ... put more configuration code here ... */

    status = _Py_InitializeMain();
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }
}
```

Memory Management

Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if they regularly manipulate object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**. This will result in mixed calls between the C allocator and the Python

memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the bytes object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

See also

The **PYTHONMALLOC** environment variable can be used to

configure the memory allocators used by Python.

The **PYTHONMALLOCSTATS** environment variable can be used to print statistics of the pymalloc memory allocator every time a new pymalloc object arena is created, and on shutdown.

Allocator Domains

All allocating functions belong to one of three different “domains” (see also **PyMemAllocatorDomain**). These domains represent different allocation strategies and are optimized for different purposes. The specific details on how every domain allocates memory or what internal functions each domain calls is considered an implementation detail, but for debugging purposes a simplified table can be found at here. There is no hard requirement to use the memory returned by the allocation functions belonging to a given domain for only the purposes hinted by that domain (although this is the recommended practice). For example, one could use the memory returned by **PyMem_RawMalloc()** for allocating Python objects or the memory returned by **PyObject_Malloc()** for allocating memory for buffers.

The three allocation domains are:

- Raw domain: intended for allocating memory for general-purpose memory buffers where the allocation *must* go to the system allocator or where the allocator can operate without the GIL. The memory is requested directly to the system.
- “Mem” domain: intended for allocating memory for Python buffers and general-purpose memory buffers where the allocation must be performed with the GIL held. The memory is taken from the Python private heap.
- Object domain: intended for allocating memory belonging to Python objects. The memory is taken from the Python private heap.

When freeing memory previously allocated by the allocating functions belonging to a given domain,the matching specific deallocating functions must be used. For example, **PyMem_Free()** must be used to free memory allocated using **PyMem_Malloc()**.

Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, the GIL does not need to be held.

The default raw memory allocator uses the following functions: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**; call `malloc(1)` (or `calloc(1, 1)`) when requesting zero bytes.

New in version 3.4.

void *PyMem_RawMalloc(size_t n)

Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawMalloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyMem_RawCalloc(size_t nelem, size_t elsize)

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawCalloc(1, 1)` had been called instead.

New in version 3.5.

void *PyMem_RawRealloc(void *p, size_t n)

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_RawMalloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned

pointer is non-NULL.

Unless *p* is NULL, it must have been returned by a previous call to **PyMem_RawMalloc()**, **PyMem_RawRealloc()** or **PyMem_RawCalloc()**.

If the request fails, **PyMem_RawRealloc()** returns NULL and *p* remains a valid pointer to the previous memory area.

void PyMem_RawFree(void *p)

Frees the memory block pointed to by *p*, which must have been returned by a previous call to **PyMem_RawMalloc()**, **PyMem_RawRealloc()** or **PyMem_RawCalloc()**. Otherwise, or if PyMem_RawFree(p) has been called before, undefined behavior occurs.

If *p* is NULL, no operation is performed.

Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

The default memory allocator uses the pymalloc memory allocator.

Warning

The GIL must be held when using these functions.

Changed in version 3.6: The default allocator is now pymalloc instead of system **malloc()**.

void *PyMem_Malloc(size_t n)

Part of the Stable ABI.
Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or NULL if the request fails.

Requesting zero bytes returns a distinct non-NULL pointer if

possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyMem_Calloc(size_t nelem, size_t elsize)

Part of the Stable ABI since version 3.7.
Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Calloc(1, 1)` had been called instead.

New in version 3.5.

void *PyMem_Realloc(void *p, size_t n)

Part of the Stable ABI.
Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to **`PyMem_Malloc()`**, **`PyMem_Realloc()`** or **`PyMem_Calloc()`**.

If the request fails, **`PyMem_Realloc()`** returns `NULL` and *p* remains a valid pointer to the previous memory area.

void PyMem_Free(void *p)

Part of the Stable ABI.
Frees the memory block pointed to by *p*, which must have been returned by a previous call to **`PyMem_Malloc()`**, **`PyMem_Realloc()`** or **`PyMem_Calloc()`**. Otherwise, or if `PyMem_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience. Note that *TYPE* refers to any C type.

TYPE *PyMem_New(TYPE, size_t n)

Same as **`PyMem_Malloc()`**, but allocates `(n * sizeof(TYPE))` bytes of memory. Returns a pointer cast to TYPE*. The memory will not have been initialized in any way.

TYPE *PyMem_Resize(void *p, TYPE, size_t n)

Same as **`PyMem_Realloc()`**, but the memory block is resized to `(n * sizeof(TYPE))` bytes. Returns a pointer cast to TYPE*. On return, *p* will be a pointer to the new memory area, or `NULL` in the event of failure.

This is a C preprocessor macro; *p* is always reassigned. Save the original value of *p* to avoid losing memory when handling errors.

void PyMem_Del(void *p)

Same as **`PyMem_Free()`**.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

- `PyMem_MALLOC(size)`
- `PyMem_NEW(type, size)`
- `PyMem_REALLOC(ptr, size)`
- `PyMem_RESIZE(ptr, type, size)`
- `PyMem_FREE(ptr)`
- `PyMem_DEL(ptr)`

Object allocators

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

Note

There is no guarantee that the memory returned by these allocators can be successfully cast to a Python object when intercepting the allocating functions in this domain by the methods described in the Customize Memory Allocators section.

The default object allocator uses the pymalloc memory allocator.

Warning

The GIL must be held when using these functions.

void *PyObject_Malloc(size_t n)

Part of the Stable ABI.
Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyObject_Calloc(size_t nelem, size_t elsize)

Part of the Stable ABI since version 3.7.
Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Calloc(1, 1)` had been called instead.

New in version 3.5.

void *PyObject_Realloc(void *p, size_t n)

Part of the Stable ABI.
Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyObject_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to **`PyObject_Malloc()`**, **`PyObject_Realloc()`** or **`PyObject_Calloc()`**.

If the request fails, **`PyObject_Realloc()`** returns `NULL` and *p* remains a valid pointer to the previous memory area.

void PyObject_Free(void *p)

Part of the Stable ABI.
Frees the memory block pointed to by *p*, which must have been returned by a previous call to **`PyObject_Malloc()`**, **`PyObject_Realloc()`** or **`PyObject_Calloc()`**. Otherwise, or if `PyObject_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

Default Memory Allocators

Default memory allocators:

Py **Py** **Py**

- Name: value for **PYTHONMALLOC** environment variable.
- `malloc`: system allocators from the standard C library, C functions: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**.
- `pymalloc`: pymalloc memory allocator.
- "+ debug": with debug hooks on the Python memory allocators.
- "Debug build": Python build in debug mode.

Customize Memory Allocators

New in version 3.4.

type PyMemAllocatorEx

Structure used to describe a memory block allocator. The structure has the following fields:

Field	Meaning
`void *ctx`	user context passed as first argument
`void* malloc(void *ctx, size_t size)`	allocate a memory block
`void* calloc(void *ctx, size_t nelem, size_t elsize)`	allocate a memory block initialized with zeros
`void* realloc(void *ctx, void *ptr, size_t new_size)`	allocate or resize a memory block
`void free(void *ctx, void *ptr)`	free a memory block

Changed in version 3.5: The **PyMemAllocator** structure was renamed to **PyMemAllocatorEx** and a new `calloc` field was added.

type PyMemAllocatorDomain

Enum used to identify an allocator domain. Domains:

PYMEM_DOMAIN_RAW

Functions:

- **PyMem_RawMalloc()**
- **PyMem_RawRealloc()**
- **PyMem_RawCalloc()**

- **PyMem_RawFree()**

PYMEM_DOMAIN_MEM
: Functions:

  - **PyMem_Malloc()**,
  - **PyMem_Realloc()**
  - **PyMem_Calloc()**
  - **PyMem_Free()**

PYMEM_DOMAIN_OBJ
: Functions:

  - **PyObject_Malloc()**
  - **PyObject_Realloc()**
  - **PyObject_Calloc()**
  - **PyObject_Free()**

void PyMem_GetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)
: Get the memory block allocator of the specified domain.

void PyMem_SetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)
: Set the memory block allocator of the specified domain.

  The new allocator must return a distinct non-`NULL` pointer when requesting zero bytes.

  For the **PYMEM_DOMAIN_RAW** domain, the allocator must be thread-safe: the GIL is not held when the allocator is called.

  If the new allocator is not a hook (does not call the previous allocator), the **PyMem_SetupDebugHooks()** function must be called to reinstall the debug hooks on top on the new allocator.

  See also **PyPreConfig.allocator** and Preinitialize Python with PyPreConfig.

Warning

PyMem_SetAllocator() does have the following contract:

- It can be called after **Py_PreInitialize()** and before **Py_InitializeFromConfig()** to install a custom memory allocator. There are no restrictions over the installed allocator other than the ones imposed by the domain (for instance, the Raw Domain allows the allocator to be called without the GIL held). See the section on allocator domains for more information.
- If called after Python has finish initializing (after **Py_InitializeFromConfig()** has been called) the allocator **must** wrap the existing allocator. Substituting the current allocator for some other arbitrary one is **not supported**.

void PyMem_SetupDebugHooks(void)

Setup debug hooks in the Python memory allocators to detect memory errors.

Debug hooks on the Python memory allocators

When Python is built in debug mode, the **PyMem_SetupDebugHooks()** function is called at the Python preinitialization to setup debug hooks on Python memory allocators to detect memory errors.

The **PYTHONMALLOC** environment variable can be used to install debug hooks on a Python compiled in release mode (ex: `PYTHONMALLOC=debug`).

The **PyMem_SetupDebugHooks()** function can be used to set debug hooks after calling **PyMem_SetAllocator()**.

These debug hooks fill dynamically allocated memory blocks with special, recognizable bit patterns. Newly allocated memory is filled with the byte `0xCD` (`PYMEM_CLEANBYTE`), freed memory is filled with the byte `0xDD` (`PYMEM_DEADBYTE`). Memory blocks are surrounded by "forbidden bytes" filled with the byte `0xFD` (`PYMEM_FORBIDDENBYTE`). Strings of these bytes are unlikely to be valid addresses, floats, or ASCII strings.

Runtime checks:

- Detect API violations. For example, detect if **PyObject_Free()** is called on a memory block allocated by **PyMem_Malloc()**.
- Detect write before the start of the buffer (buffer underflow).
- Detect write after the end of the buffer (buffer overflow).
- Check that the GIL is held when allocator functions of **PYMEM_DOMAIN_OBJ** (ex: **PyObject_Malloc()**) and **PYMEM_DOMAIN_MEM** (ex: **PyMem_Malloc()**) domains are called.

On error, the debug hooks use the **tracemalloc** module to get the traceback where a memory block was allocated. The traceback is only displayed if **tracemalloc** is tracing Python memory allocations and the memory block was traced.

Let *S* = `sizeof(size_t)`. `2*S` bytes are added at each end of each block of *N* bytes requested. The memory layout is like so, where p represents the address returned by a malloc-like or realloc-like function (`p[i:j]` means the slice of bytes from `*(p+i)` inclusive up to `*(p+j)` exclusive; note that the treatment of negative indices differs from a Python slice):

`p[-2*S:-S]`

Number of bytes originally asked for. This is a size_t, big-

endian (easier to read in a memory dump).

`p[-S]`

API identifier (ASCII character):

- `'r'` for **`PYMEM_DOMAIN_RAW`**.
- `'m'` for **`PYMEM_DOMAIN_MEM`**.
- `'o'` for **`PYMEM_DOMAIN_OBJ`**.

`p[-S+1:0]`

Copies of PYMEM_FORBIDDENBYTE. Used to catch under-writes and reads.

`p[0:N]`

The requested memory, filled with copies of PYMEM_CLEANBYTE, used to catch reference to uninitialized memory. When a realloc-like function is called requesting a larger memory block, the new excess bytes are also filled with PYMEM_CLEANBYTE. When a free-like function is called, these are overwritten with PYMEM_DEADBYTE, to catch reference to freed memory. When a realloc- like function is called requesting a smaller memory block, the excess old bytes are also filled with PYMEM_DEADBYTE.

`p[N:N+S]`

Copies of PYMEM_FORBIDDENBYTE. Used to catch over-writes and reads.

`p[N+S:N+2*S]`

Only used if the `PYMEM_DEBUG_SERIALNO` macro is defined (not defined by default).

A serial number, incremented by 1 on each call to a malloc-like or realloc-like function. Big-endian `size_t`. If “bad memory” is detected later, the serial number gives an excellent way to set a breakpoint on the next run, to capture the instant at which this block was passed out. The static function bumpserialno() in obmalloc.c is the only place the serial number is incremented, and exists so you can set such a breakpoint easily.

A realloc-like or free-like function first checks that the PYMEM_FORBIDDENBYTE bytes at each end are intact. If they've been altered, diagnostic output is written to stderr, and the program is aborted via Py_FatalError(). The other main failure mode is provoking a memory error when a program reads up one of the special bit patterns and tries to use it as an address. If you get in a debugger then and look at the object, you're likely to see that it's entirely filled with PYMEM_DEADBYTE (meaning freed memory is getting used) or PYMEM_CLEANBYTE (meaning uninitialized memory is getting used).

Changed in version 3.6: The **PyMem_SetupDebugHooks()** function now also works on Python compiled in release mode. On error, the debug hooks now use **tracemalloc** to get the traceback where a memory block was allocated. The debug hooks now also check if the GIL is held when functions of **PYMEM_DOMAIN_OBJ** and **PYMEM_DOMAIN_MEM** domains are called.

Changed in version 3.8: Byte patterns `0xCB` (`PYMEM_CLEANBYTE`), `0xDB` (`PYMEM_DEADBYTE`) and `0xFB` (`PYMEM_FORBIDDENBYTE`) have been replaced with `0xCD`, `0xDD` and `0xFD` to use the same values than Windows CRT debug `malloc()` and `free()`.

The pymalloc allocator

Python has a *pymalloc* allocator optimized for small objects (smaller or equal to 512 bytes) with a short lifetime. It uses memory mappings called "arenas" with a fixed size of 256 KiB. It falls back to **PyMem_RawMalloc()** and **PyMem_RawRealloc()** for allocations larger than 512 bytes.

pymalloc is the default allocator of the **PYMEM_DOMAIN_MEM** (ex: **PyMem_Malloc()**) and **PYMEM_DOMAIN_OBJ** (ex: **PyObject_Malloc()**) domains.

The arena allocator uses the following functions:

- **VirtualAlloc()** and **VirtualFree()** on Windows,
- **mmap()** and **munmap()** if available,
- **malloc()** and **free()** otherwise.

This allocator is disabled if Python is configured with the **--without-pymalloc** option. It can also be disabled at runtime using the **PYTHONMALLOC** environment variable (ex: `PYTHONMALLOC=malloc`).

Customize pymalloc Arena Allocator

New in version 3.4.

type PyObjectArenaAllocator

Structure used to describe an arena allocator. The structure has three fields:

Member	Meaning
`ctx`	user context passed as first argument
`alloc`	allocate an arena of size bytes, `void* alloc(void *ctx, size_t size)`
`free`	free an arena, `void free(void *ctx, void *ptr, size_t size)`

void PyObject_GetArenaAllocator(PyObjectArenaAllocator *allocator)

Get the arena allocator.

void PyObject_SetArenaAllocator(PyObjectArenaAllocator *allocator)

Set the arena allocator.

tracemalloc C API

New in version 3.7.

int PyTraceMalloc_Track(unsigned int domain, uintptr_t ptr, size_t size)

Track an allocated memory block in the **tracemalloc** module.

Return `0` on success, return `-1` on error (failed to allocate memory to store the trace). Return `-2` if tracemalloc is

disabled.

If memory block is already tracked, update the existing trace.

int PyTraceMalloc_Untrack(unsigned int domain, uintptr_t ptr)

Untrack an allocated memory block in the **tracemalloc** module. Do nothing if the block was not tracked.

Return `-2` if tracemalloc is disabled, otherwise return `0`.

Examples

Here is the example from section Overview, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always

manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3);  /* Wrong -- should be PyMem_Free() */
free(buf2);       /* Right -- allocated via malloc() */
free(buf1);       /* Fatal -- should be PyMem_Del()  */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with **`PyObject_New()`**, **`PyObject_NewVar()`** and **`PyObject_Del()`**.

These will be explained in the next chapter on defining and implementing new object types in C.

Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

  - Controlling the Garbage Collector State

Allocating Objects on the Heap

PyObject *_PyObject_New(PyTypeObject *type)

Return value: New reference.

PyVarObject *_PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)

Return value: New reference.

PyObject *PyObject_Init(PyObject *op, PyTypeObject *type)

Return value: Borrowed reference. Part of the Stable ABI.
Initialize a newly allocated object *op* with its type and initial reference. Returns the initialized object. If *type* indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

PyVarObject *PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)

Return value: Borrowed reference. Part of the Stable ABI.
This does everything **`PyObject_Init()`** does, and also initializes the length information for a variable-size object.

TYPE *PyObject_New(TYPE, PyTypeObject *type)

Return value: New reference.
Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the **`tp_basicsize`** field of the type object.

TYPE *PyObject_NewVar(TYPE, PyTypeObject *type, Py_ssize_t

size)

Return value: New reference.
Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized. The allocated memory allows for the *TYPE* structure plus *size* fields of the size given by the **tp_itemsize** field of *type*. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void PyObject_Del(void *op)

Releases memory allocated to an object using **PyObject_New()** or **PyObject_NewVar()**. This is normally called from the **tp_dealloc** handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

PyObject _Py_NoneStruct

Object which is visible in Python as `None`. This should only be accessed using the **Py_None** macro, which evaluates to a pointer to this object.

See also

PyModule_Create()
To allocate and create extension modules.

Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

Base object types and macros

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the **PyObject** and **PyVarObject** types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

type PyObject

Part of the Limited API. (Only some members are part of the stable ABI.)
All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal "release" build, it contains only the object's reference count and a pointer to the corresponding type object. Nothing is actually declared to be a **PyObject**, but every pointer to a Python object can be cast to a PyObject*. Access to the members must be done by using the macros **Py_REFCNT** and **Py_TYPE**.

type PyVarObject

Part of the Limited API. (Only some members are part of the stable ABI.)
This is an extension of **PyObject** that adds the **ob_size** field. This is only used for objects that have some notion of *length*. This type does not often appear in the Python/C API. Access to the members must be done by using the macros **Py_REFCNT**, **Py_TYPE**, and **Py_SIZE**.

PyObject_HEAD

This is a macro used when declaring new types which represent objects without a varying length. The PyObject_HEAD macro expands to:

```
PyObject ob_base;
```

See documentation of **`PyObject`** above.

PyObject_VAR_HEAD

This is a macro used when declaring new types which represent objects with a length that varies from instance to instance. The PyObject_VAR_HEAD macro expands to:

```
PyVarObject ob_base;
```

See documentation of **`PyVarObject`** above.

int Py_Is(PyObject *x, PyObject *y)

Part of the Stable ABI since version 3.10.
Test if the *x* object is the *y* object, the same as `x is y` in Python.

New in version 3.10.

int Py_IsNone(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `None` singleton, the same as `x is None` in Python.

New in version 3.10.

int Py_IsTrue(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `True` singleton, the same as `x is True` in Python.

New in version 3.10.

int Py_IsFalse(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `False` singleton, the same as `x is False` in Python.

New in version 3.10.

PyTypeObject *Py_TYPE(PyObject *o)

Get the type of the Python object *o*.

Return a borrowed reference.

Use the **`Py_SET_TYPE()`** function to set an object type.

Changed in version 3.11: **`Py_TYPE()`** is changed to an inline static function. The parameter type is no longer const PyObject*.

int Py_IS_TYPE(PyObject *o, PyTypeObject *type)

Return non-zero if the object *o* type is *type*. Return zero otherwise. Equivalent to: `Py_TYPE(o) == type`.

New in version 3.9.

void Py_SET_TYPE(PyObject *o, PyTypeObject *type)

Set the object *o* type to *type*.

New in version 3.9.

Py_ssize_t Py_REFCNT(PyObject *o)

Get the reference count of the Python object *o*.

Use the **`Py_SET_REFCNT()`** function to set an object reference count.

Changed in version 3.11: The parameter type is no longer const PyObject*.

Changed in version 3.10: **`Py_REFCNT()`** is changed to the

inline static function.

void Py_SET_REFCNT(PyObject *o, Py_ssize_t refcnt)

Set the object *o* reference counter to *refcnt*.

New in version 3.9.

Py_ssize_t Py_SIZE(PyVarObject *o)

Get the size of the Python object *o*.

Use the **Py_SET_SIZE()** function to set an object size.

Changed in version 3.11: **Py_SIZE()** is changed to an inline static function. The parameter type is no longer const PyVarObject*.

void Py_SET_SIZE(PyVarObject *o, Py_ssize_t size)

Set the object *o* size to *size*.

New in version 3.9.

PyObject_HEAD_INIT(type)

This is a macro which expands to initialization values for a new **PyObject** type. This macro expands to:

```
_PyObject_EXTRA_INIT
1, type,
```

PyVarObject_HEAD_INIT(type, size)

This is a macro which expands to initialization values for a new **PyVarObject** type, including the **ob_size** field. This macro expands to:

```
_PyObject_EXTRA_INIT
1, type, size,
```

Implementing functions and methods

type PyCFunction

Part of the Stable ABI.
Type of the functions used to implement most Python callables in C. Functions of this type take two PyObject* parameters and return one such value. If the return value is NULL, an exception shall have been set. If not NULL, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

The function signature is:

```
PyObject *PyCFunction(PyObject *self,
                      PyObject *args);
```

type PyCFunctionWithKeywords

Part of the Stable ABI.
Type of the functions used to implement Python callables in C with signature **METH_VARARGS | METH_KEYWORDS**. The function signature is:

```
PyObject *PyCFunctionWithKeywords(PyObject *self,
                                  PyObject *args,
                                  PyObject *kwargs)
```

type _PyCFunctionFast

Type of the functions used to implement Python callables in C with signature **METH_FASTCALL**. The function signature is:

```
PyObject *_PyCFunctionFast(PyObject *self,
                           PyObject *const *args,
                           Py_ssize_t nargs);
```

type _PyCFunctionFastWithKeywords

Type of the functions used to implement Python callables in C with signature **METH_FASTCALL | METH_KEYWORDS**. The function signature is:

```
PyObject *_PyCFunctionFastWithKeywords(PyObject *se
```

```
                                    PyObject *co
                                    Py_ssize_t n
                                    PyObject *kw
```

type PyCMethod

Type of the functions used to implement Python callables in C with signature **METH_METHOD | METH_FASTCALL | METH_KEYWORDS**. The function signature is:

```
PyObject *PyCMethod(PyObject *self,
                    PyTypeObject *defining_class,
                    PyObject *const *args,
                    Py_ssize_t nargs,
                    PyObject *kwnames)
```

New in version 3.9.

type PyMethodDef

Part of the Stable ABI (including all members).
Structure used to describe a method of an extension type. This structure has four fields:

Member	Meaning
const char *ml_name	name of the method
PyCFunction ml_meth	pointer to the C implementation
int ml_flags	flag bits indicating how the call should be constructed
const char *ml_doc	points to the contents of the docstring

The **ml_meth** is a C function pointer. The functions may be of different types, but they always return PyObject*. If the function is not of the **PyCFunction**, the compiler will require a cast in the method table. Even though **PyCFunction** defines the first parameter as PyObject*, it is common that the method implementation uses the specific C type of the *self* object.

The **ml_flags** field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention.

There are these calling conventions:

METH_VARARGS

This is the typical calling convention, where the methods have the type **PyCFunction**. The function expects two PyObject* values. The first one is the *self* object for methods; for module functions, it is the module object. The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using **PyArg_ParseTuple()** or **PyArg_UnpackTuple()**.

METH_VARARGS | METH_KEYWORDS

Methods with these flags must be of type **PyCFunctionWithKeywords**. The function expects three parameters: *self*, *args*, *kwargs* where *kwargs* is a dictionary of all the keyword arguments or possibly `NULL` if there are no keyword arguments. The parameters are typically processed using **PyArg_ParseTupleAndKeywords()**.

METH_FASTCALL

Fast calling convention supporting only positional arguments. The methods have the type **_PyCFunctionFast**. The first parameter is *self*, the second parameter is a C array of PyObject* values indicating the arguments and the third parameter is the number of arguments (the length of the array).

New in version 3.7.

Changed in version 3.10: `METH_FASTCALL` is now part of the stable ABI.

METH_FASTCALL | METH_KEYWORDS

Extension of **METH_FASTCALL** supporting also keyword arguments, with methods of type **_PyCFunctionFastWithKeywords**. Keyword arguments are passed the same way as in the vectorcall protocol: there is an additional fourth PyObject* parameter which is a tuple representing the names of the keyword arguments (which are guaranteed to be strings) or possibly `NULL` if there are no keywords. The values of the keyword arguments are stored in

the *args* array, after the positional arguments.

New in version 3.7.

METH_METHOD | METH_FASTCALL | METH_KEYWORDS

Extension of **METH_FASTCALL | METH_KEYWORDS** supporting the *defining class*, that is, the class that contains the method in question. The defining class might be a superclass of `Py_TYPE(self)`.

The method needs to be of type **PyCMethod**, the same as for `METH_FASTCALL | METH_KEYWORDS` with `defining_class` argument added after `self`.

New in version 3.9.

METH_NOARGS

Methods without parameters don't need to check whether arguments are given if they are listed with the **METH_NOARGS** flag. They need to be of type **PyCFunction**. The first parameter is typically named *self* and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

The function must have 2 parameters. Since the second parameter is unused, **Py_UNUSED** can be used to prevent a compiler warning.

METH_O

Methods with a single object argument can be listed with the **METH_O** flag, instead of invoking **PyArg_ParseTuple()** with a `"O"` argument. They have the type **PyCFunction**, with the *self* parameter, and a PyObject* parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

METH_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the **`classmethod()`** built-in function.

METH_STATIC

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the **`staticmethod()`** built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

METH_COEXIST

The method will be loaded in place of existing definitions. Without *METH_COEXIST*, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a *sq_contains* slot, for example, would generate a wrapped method named **`__contains__()`** and preclude the loading of a corresponding PyCFunction with the same name. With the flag defined, the PyCFunction will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to PyCFunctions are optimized more than wrapper object calls.

Accessing attributes of extension types

type PyMemberDef

Part of the Stable ABI (including all members).
Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are:

Member	Meaning
name	name of the member
type	the type of the member in the C struct
offset	byte offset in bytes that the member is located on the type's

object struct	
flags bits	bits indicating if the field should be read-only or writable
doc const char *	points to the contents of the docstring

type can be one of many `T_` macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type.

Macro name	Type
T_SHORT	short
T_INT	int
T_LONG	long
T_FLOAT	float
T_DOUBLE	double
T_STRING	const char *
T_OBJECT	PyObject *
T_OBJECT_EX	PyObject *
T_CHAR	char
T_BYTE	char
T_UBYTE	unsigned char
T_UINT	unsigned int
T_USHORT	unsigned short
T_ULONG	unsigned long
T_BOOL	char
T_LONGLONG	long long
T_ULONGLONG	unsigned long long
T_PYSSIZET	Py_ssize_t

T_OBJECT and **T_OBJECT_EX** differ in that **T_OBJECT** returns `None` if the member is `NULL` and **T_OBJECT_EX** raises an **AttributeError**. Try to use **T_OBJECT_EX** over **T_OBJECT** because **T_OBJECT_EX** handles use of the **del** statement on that attribute more correctly than **T_OBJECT**.

flags can be `0` for write and read access or **READONLY** for read-only access. Using **T_STRING** for **type** implies **READONLY**. **T_STRING** data is interpreted as UTF-8. Only **T_OBJECT** and **T_OBJECT_EX** members can be deleted. (They are set to `NULL`).

Heap allocated types (created using **PyType_FromSpec()** or similar), `PyMemberDef` may contain definitions for the special members `__dictoffset__`, `__weaklistoffset__` and `__vectorcalloffset__`, corresponding to **tp_dictoffset**, **tp_weaklistoffset** and **tp_vectorcall_offset** in type objects. These must be defined with `T_PYSSIZET` and `READONLY`, for example:

```
static PyMemberDef spam_type_members[] = {
    {"__dictoffset__", T_PYSSIZET, offsetof(Spam_ob
    {NULL}  /* Sentinel */
};
```

PyObject *PyMember_GetOne(const char *obj_addr, struct PyMemberDef *m)

Get an attribute belonging to the object at address *obj_addr*. The attribute is described by `PyMemberDef` *m*. Returns `NULL` on error.

int PyMember_SetOne(char *obj_addr, struct PyMemberDef *m, PyObject *o)

Set an attribute belonging to the object at address *obj_addr* to object *o*. The attribute to set is described by `PyMemberDef` *m*. Returns `0` if successful and a negative value on failure.

type PyGetSetDef

Part of the Stable ABI (including all members).
Structure to define property-like access for a type. See also description of the **PyTypeObject.tp_getset** slot.

Member	Meaning
name	attribute name
get	C function to get the attribute
set	optional C function to set or delete the attribute, if omitted the attribute is readonly
doc	optional docstring
closure	optional function pointer, providing additional data for getter and setter

The `get` function takes one PyObject* parameter (the instance) and a function pointer (the associated `closure`):

```
typedef PyObject *(*getter)(PyObject *, void *);
```

It should return a new reference on success or `NULL` with a set exception on failure.

`set` functions take two PyObject* parameters (the instance and the value to be set) and a function pointer (the associated `closure`):

```
typedef int (*setter)(PyObject *, PyObject *, void
```

In case the attribute should be deleted the second parameter is `NULL`. Should return `0` on success or `-1` with a set exception on failure.

Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the **PyTypeObject** structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

In addition to the following quick reference, the Examples section provides at-a-glance insight into the meaning and use of **PyTypeObject**.

Quick Reference

"tp slots"

PyTypeObject Slot	Type	special methods/attrs
tp_name	char *	__name__
tp_basicsize	Py_ssize_t	
tp_itemsize	Py_ssize_t	
tp_dealloc	destructor	
tp_vectorcall_offset	Py_ssize_t	
tp_getattr	getattrfunc	__getattribute__, __getattr__
tp_setattr	setattrfunc	__setattr__, __delattr__
tp_as_async	PyAsyncMethods *	

[1]

(): A slot name in parentheses indicates it is (effectively) deprecated.

<>: Names in angle brackets should be initially set to `NULL` and treated as read-only.

[]: Names in square brackets are for internal use only.

<R> (as a prefix) means the field is required (must be non-`NULL`).

[2]

Columns:

"O": set on **`PyBaseObject_Type`**

"T": set on **`PyType_Type`**

"D": default (if slot is set to `NULL`)

```
X - PyType_Ready sets this value if it is NULL
~ - PyType_Ready always sets this value (it should be
? - PyType_Ready may set this value depending on othe

Also see the inheritance column ("I").
```

"I": inheritance

```
X - type slot is inherited via *PyType_Ready* if defi
% - the slots of the sub-struct are inherited indivic
G - inherited, but only in combination with other slo
? - it's complicated; see the slot's description
```

Note that some slots are effectively inherited through the normal attribute lookup chain.

PyTypeObject Definition

The structure definition for `PyTypeObject` can be found in

`Include/object.h`. For convenience of reference, this repeats the definition found there:

```
typedef struct _typeobject {

```

PyObject Slots

The type object structure extends the **PyVarObject** structure. The **ob_size** field is used for dynamic types (created by **type_new()**, usually called from a class statement). Note that **PyType_Type** (the metatype) initializes **tp_itemsize**, which means that its instances (i.e. type objects) *must* have the **ob_size** field.

Py_ssize_t PyObject.ob_refcnt

Part of the Stable ABI.
This is the type object's reference count, initialized to `1` by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose **ob_type** points back to the type) do *not* count as references. But for dynamically allocated type objects, the instances *do* count as references.

Inheritance:

This field is not inherited by subtypes.

PyTypeObject *PyObject.ob_type

Part of the Stable ABI.
This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is

to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. **`PyType_Ready()`** checks if **`ob_type`** is `NULL`, and if so, initializes it to the **`ob_type`** field of the base class. **`PyType_Ready()`** will not change this field if it is non-zero.

Inheritance:

This field is inherited by subtypes.

PyObject *PyObject._ob_next
PyObject *PyObject._ob_prev

These fields are only present when the macro `Py_TRACE_REFS` is defined (see the **`configure --with-trace-refs option`**).

Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly linked list of *all* live objects on the heap.

This could be used for various debugging purposes; currently the only uses are the **`sys.getobjects()`** function and to print the objects that are still alive at the end of a run when the environment variable **`PYTHONDUMPREFS`** is set.

Inheritance:

These fields are not inherited by subtypes.

PyVarObject Slots

Py_ssize_t PyVarObject.ob_size

Part of the Stable ABI.
For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

Inheritance:

This field is not inherited by subtypes.

PyTypeObject Slots

Each slot has a section describing inheritance. If **PyType_Ready()** may set a value when the field is set to `NULL` then there will also be a "Default" section. (Note that many fields set on **PyBaseObject_Type** and **PyType_Type** effectively act as defaults.)

const char *PyTypeObject.tp_name

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named **T** defined in module **M** in subpackage **Q** in package **P** should have the **tp_name** initializer `"P.Q.M.T"`.

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For statically allocated type objects, the *tp_name* field should contain a dot. Everything before the last dot is made accessible as the **__module__** attribute, and everything after the last dot is made accessible as the **__name__** attribute.

If no dot is present, the entire **tp_name** field is made accessible as the **__name__** attribute, and the **__module__** attribute is undefined (unless explicitly set in the dictionary,

as explained above). This means your type will be impossible to pickle. Additionally, it will not be listed in module documentations created with pydoc.

This field must not be `NULL`. It is the only required field in **`PyTypeObject()`** (other than potentially **`tp_itemsize`**).

Inheritance:

This field is not inherited by subtypes.

Py_ssize_t PyTypeObject.tp_basicsize
Py_ssize_t PyTypeObject.tp_itemsize

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero **`tp_itemsize`** field, types with variable-length instances have a non-zero **`tp_itemsize`** field. For a type with fixed-length instances, all instances have the same size, given in **`tp_basicsize`**.

For a type with variable-length instances, the instances must have an **`ob_size`** field, and the instance size is **`tp_basicsize`** plus N times **`tp_itemsize`**, where N is the "length" of the object. The value of N is typically stored in the instance's **`ob_size`** field. There are exceptions: for example, ints use a negative **`ob_size`** to indicate a negative number, and N is `abs(ob_size)` there. Also, the presence of an **`ob_size`** field in the instance layout doesn't mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful **`ob_size`** field).

The basic size includes the fields in the instance declared by the macro **`PyObject_HEAD`** or **`PyObject_VAR_HEAD`** (whichever is used to declare the instance struct) and this in turn includes the **`_ob_prev`** and **`_ob_next`** fields if they are present. This means that the only correct way to get an initializer for the **`tp_basicsize`** is to use the `sizeof` operator on the struct used to declare the instance layout. The

basic size does not include the GC header size.

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of **`tp_basicsize`**. Example: suppose a type implements an array of `double`. **`tp_itemsize`** is `sizeof(double)`. It is the programmer's responsibility that **`tp_basicsize`** is a multiple of `sizeof(double)` (assuming this is the alignment requirement for `double`).

For any type with variable-length instances, this field must not be `NULL`.

Inheritance:

These fields are inherited separately by subtypes. If the base type has a non-zero **`tp_itemsize`**, it is generally not safe to set **`tp_itemsize`** to a different non-zero value in a subtype (though this depends on the implementation of the base type).

destructor PyTypeObject.tp_dealloc

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`). The function signature is:

```
void tp_dealloc(PyObject *self);
```

The destructor function is called by the **`Py_DECREF()`** and **`Py_XDECREF()`** macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and call the type's **`tp_free`** function. If the type is not subtypable (doesn't have the **`Py_TPFLAGS_BASETYPE`** flag bit set), it is permissible to call the object deallocator directly instead of via **`tp_free`**. The object deallocator should be the one used to allocate the instance; this is

normally **PyObject_Del()** if the instance was allocated using **PyObject_New()** or **PyObject_VarNew()**, or **PyObject_GC_Del()** if the instance was allocated using **PyObject_GC_New()** or **PyObject_GC_NewVar()**.

If the type supports garbage collection (has the **Py_TPFLAGS_HAVE_GC** flag bit set), the destructor should call **PyObject_GC_UnTrack()** before clearing any member fields.

```
static void foo_dealloc(foo_object *self) {
    PyObject_GC_UnTrack(self);
    Py_CLEAR(self->ref);
    Py_TYPE(self)->tp_free((PyObject *)self);
}
```

Finally, if the type is heap allocated (**Py_TPFLAGS_HEAPTYPE**), the deallocator should decrement the reference count for its type object after calling the type deallocator. In order to avoid dangling pointers, the recommended way to achieve this is:

```
static void foo_dealloc(foo_object *self) {
    PyTypeObject *tp = Py_TYPE(self);
    // free references and buffers here
    tp->tp_free(self);
    Py_DECREF(tp);
}
```

Inheritance:

This field is inherited by subtypes.

Py_ssize_t PyTypeObject.tp_vectorcall_offset

An optional offset to a per-instance function that implements calling the object using the vectorcall protocol, a more efficient alternative of the simpler **tp_call**.

This field is only used if the flag **Py_TPFLAGS_HAVE_VECTORCALL** is set. If so, this must be a

positive integer containing the offset in the instance of a **vectorcallfunc** pointer.

The *vectorcallfunc* pointer may be `NULL`, in which case the instance behaves as if **Py_TPFLAGS_HAVE_VECTORCALL** was not set: calling the instance falls back to **tp_call**.

Any class that sets `Py_TPFLAGS_HAVE_VECTORCALL` must also set **tp_call** and make sure its behaviour is consistent with the *vectorcallfunc* function. This can be done by setting *tp_call* to **PyVectorcall_Call()**.

Warning

It is not recommended for mutable heap types to implement the vectorcall protocol. When a user sets **__call__** in Python code, only *tp_call* is updated, likely making it inconsistent with the vectorcall function.

Changed in version 3.8: Before version 3.8, this slot was named `tp_print`. In Python 2.x, it was used for printing to a file. In Python 3.0 to 3.7, it was unused.

Inheritance:

This field is always inherited. However, the **Py_TPFLAGS_HAVE_VECTORCALL** flag is not always inherited. If it's not, then the subclass won't use vectorcall, except when **PyVectorcall_Call()** is explicitly called. This is in particular the case for types without the **Py_TPFLAGS_IMMUTABLETYPE** flag set (including subclasses defined in Python).

getattrfunc PyTypeObject.tp_getattr

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the **tp_getattro** function, but taking a C string instead of a Python string object to give the attribute name.

Inheritance:

Group: **tp_getattr**, **tp_getattro**

This field is inherited by subtypes together with **tp_getattro**: a subtype inherits both **tp_getattr** and **tp_getattro** from its base type when the subtype's **tp_getattr** and **tp_getattro** are both `NULL`.

setattrfunc PyTypeObject.tp_setattr

An optional pointer to the function for setting and deleting attributes.

This field is deprecated. When it is defined, it should point to a function that acts the same as the **tp_setattro** function, but taking a C string instead of a Python string object to give the attribute name.

Inheritance:

Group: **tp_setattr**, **tp_setattro**

This field is inherited by subtypes together with **tp_setattro**: a subtype inherits both **tp_setattr** and **tp_setattro** from its base type when the subtype's **tp_setattr** and **tp_setattro** are both `NULL`.

PyAsyncMethods *PyTypeObject.tp_as_async

Pointer to an additional structure that contains fields relevant only to objects which implement awaitable and asynchronous iterator protocols at the C-level. See Async Object Structures for details.

New in version 3.5: Formerly known as `tp_compare` and `tp_reserved`.

Inheritance:

The **tp_as_async** field is not inherited, but the contained fields are inherited individually.

reprfunc PyTypeObject.tp_repr

An optional pointer to a function that implements the built-in function **`repr()`**.

The signature is the same as for **`PyObject_Repr()`**:

```
PyObject *tp_repr(PyObject *self);
```

The function must return a string or a Unicode object. Ideally, this function should return a string that, when passed to **`eval()`**, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<'` and ending with `'>'` from which both the type and the value of the object can be deduced.

Inheritance:

This field is inherited by subtypes.

Default:

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object's memory address.

PyNumberMethods *PyTypeObject.tp_as_number

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in Number Object Structures.

Inheritance:

The **`tp_as_number`** field is not inherited, but the contained fields are inherited individually.

PySequenceMethods *PyTypeObject.tp_as_sequence

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in Sequence Object Structures.

Inheritance:

The **tp_as_sequence** field is not inherited, but the contained fields are inherited individually.

PyMappingMethods *PyTypeObject.tp_as_mapping

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in Mapping Object Structures.

Inheritance:

The **tp_as_mapping** field is not inherited, but the contained fields are inherited individually.

hashfunc PyTypeObject.tp_hash

An optional pointer to a function that implements the built-in function **hash()**.

The signature is the same as for **PyObject_Hash()**:

```
Py_hash_t tp_hash(PyObject *);
```

The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

When this field is not set (*and* **tp_richcompare** is not set), an attempt to take the hash of the object raises **TypeError**. This is the same as setting it to **PyObject_HashNotImplemented()**.

This field can be set explicitly to **PyObject_HashNotImplemented()** to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to **PyObject_HashNotImplemented()**.

Inheritance:

Group: **tp_hash**, **tp_richcompare**

This field is inherited by subtypes together with **tp_richcompare**: a subtype inherits both of **tp_richcompare** and **tp_hash**, when the subtype's **tp_richcompare** and **tp_hash** are both NULL.

ternaryfunc PyTypeObject.tp_call

An optional pointer to a function that implements calling the object. This should be NULL if the object is not callable. The signature is the same as for **PyObject_Call()**:

```
PyObject *tp_call(PyObject *self, PyObject *args, P
```

Inheritance:

This field is inherited by subtypes.

reprfunc PyTypeObject.tp_str

An optional pointer to a function that implements the built-in operation **str()**. (Note that **str** is a type now, and **str()** calls the constructor for that type. This constructor calls **PyObject_Str()** to do the actual work, and **PyObject_Str()** will call this handler.)

The signature is the same as for **PyObject_Str()**:

```
PyObject *tp_str(PyObject *self);
```

The function must return a string or a Unicode object. It should be a "friendly" string representation of the object, as this is the representation that will be used, among other things, by the **print()** function.

Inheritance:

This field is inherited by subtypes.

Default:

When this field is not set, **PyObject_Repr()** is called to return a string representation.

getattrofunc PyTypeObject.tp_getattro

An optional pointer to the get-attribute function.

The signature is the same as for **PyObject_GetAttr()**:

```
PyObject *tp_getattro(PyObject *self, PyObject *att
```

It is usually convenient to set this field to **PyObject_GenericGetAttr()**, which implements the normal way of looking for object attributes.

Inheritance:

Group: **tp_getattr**, **tp_getattro**

This field is inherited by subtypes together with **tp_getattr**: a subtype inherits both **tp_getattr** and **tp_getattro** from its base type when the subtype's **tp_getattr** and **tp_getattro** are both `NULL`.

Default:

PyBaseObject_Type uses **PyObject_GenericGetAttr()**.

setattrofunc PyTypeObject.tp_setattro

An optional pointer to the function for setting and deleting attributes.

The signature is the same as for **PyObject_SetAttr()**:

```
int tp_setattro(PyObject *self, PyObject *attr, PyO
```

In addition, setting *value* to `NULL` to delete an attribute must be supported. It is usually convenient to set this field to **PyObject_GenericSetAttr()**, which implements the normal way of setting object attributes.

Inheritance:

Group: **tp_setattr**, **tp_setattro**

This field is inherited by subtypes together with **tp_setattr**: a subtype inherits both **tp_setattr** and **tp_setattro** from its base type when the subtype's **tp_setattr** and **tp_setattro** are both `NULL`.

Default:

PyBaseObject_Type uses **PyObject_GenericSetAttr()**.

PyBufferProcs *PyTypeObject.tp_as_buffer

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in Buffer Object Structures.

Inheritance:

The **tp_as_buffer** field is not inherited, but the contained fields are inherited individually.

unsigned long PyTypeObject.tp_flags

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via **tp_as_number**, **tp_as_sequence**, **tp_as_mapping**, and **tp_as_buffer**) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

Inheritance:

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension

structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The **Py_TPFLAGS_HAVE_GC** flag bit is inherited together with the **tp_traverse** and **tp_clear** fields, i.e. if the **Py_TPFLAGS_HAVE_GC** flag bit is clear in the subtype and the **tp_traverse** and **tp_clear** fields in the subtype exist and have `NULL` values.

Default:

PyBaseObject_Type uses `Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE`.

Bit Masks:

The following bit masks are currently defined; these can be ORed together using the `|` operator to form the value of the **tp_flags** field. The macro **PyType_HasFeature()** takes a type and a flags value, *tp* and *f*, and checks whether `tp->tp_flags & f` is non-zero.

Py_TPFLAGS_HEAPTYPE

This bit is set when the type object itself is allocated on the heap, for example, types created dynamically using **PyType_FromSpec()**. In this case, the **ob_type** field of its instances is considered a reference to the type, and the type object is INCREF'ed when a new instance is created, and DECREF'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's ob_type gets INCREF'ed or DECREF'ed).

Inheritance:

???

Py_TPFLAGS_BASETYPE

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a "final" class in Java).

Inheritance:

???

Py_TPFLAGS_READY

This bit is set when the type object has been fully initialized by **`PyType_Ready()`**.

Inheritance:

???

Py_TPFLAGS_READYING

This bit is set while **`PyType_Ready()`** is in the process of initializing the type object.

Inheritance:

???

Py_TPFLAGS_HAVE_GC

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using **`PyObject_GC_New()`** and destroyed using **`PyObject_GC_Del()`**. More information in section Supporting Cyclic Garbage Collection. This bit also implies that the GC-related fields **`tp_traverse`** and **`tp_clear`** are present in the type object.

Inheritance:

Group: **`Py_TPFLAGS_HAVE_GC`**, **`tp_traverse`**, **`tp_clear`**

The **`Py_TPFLAGS_HAVE_GC`** flag bit is inherited together with the **`tp_traverse`** and **`tp_clear`** fields, i.e. if the **`Py_TPFLAGS_HAVE_GC`** flag bit is clear in the subtype and the **`tp_traverse`** and **`tp_clear`** fields in the subtype exist and have `NULL` values.

Py_TPFLAGS_DEFAULT

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:
Py_TPFLAGS_HAVE_STACKLESS_EXTENSION.

Inheritance:

???

Py_TPFLAGS_METHOD_DESCRIPTOR

This bit indicates that objects behave like unbound methods.

If this flag is set for `type(meth)`, then:

- `meth.__get__(obj, cls)(*args, **kwds)` (with `obj` not None) must be equivalent to `meth(obj, *args, **kwds)`.
- `meth.__get__(None, cls)(*args, **kwds)` must be equivalent to `meth(*args, **kwds)`.

This flag enables an optimization for typical method calls like `obj.meth()`: it avoids creating a temporary "bound method" object for `obj.meth`.

New in version 3.8.

Inheritance:

This flag is never inherited by types without the **Py_TPFLAGS_IMMUTABLETYPE** flag set. For extension types, it is inherited whenever **tp_descr_get** is inherited.

Py_TPFLAGS_LONG_SUBCLASS

Py_TPFLAGS_LIST_SUBCLASS

Py_TPFLAGS_TUPLE_SUBCLASS

Py_TPFLAGS_BYTES_SUBCLASS

Py_TPFLAGS_UNICODE_SUBCLASS

Py_TPFLAGS_DICT_SUBCLASS

Py_TPFLAGS_BASE_EXC_SUBCLASS

Py_TPFLAGS_TYPE_SUBCLASS

These flags are used by functions such as **`PyLong_Check()`** to quickly determine if a type is a subclass of a built-in type; such specific checks are faster than a generic check, like **`PyObject_IsInstance()`**. Custom types that inherit from built-ins should have their **`tp_flags`** set appropriately, or the code that interacts with such types will behave differently depending on what kind of check is used.

Py_TPFLAGS_HAVE_FINALIZE

This bit is set when the **`tp_finalize`** slot is present in the type structure.

New in version 3.4.

Deprecated since version 3.8: This flag isn't necessary anymore, as the interpreter assumes the **`tp_finalize`** slot is always present in the type structure.

Py_TPFLAGS_HAVE_VECTORCALL

This bit is set when the class implements the vectorcall protocol. See **`tp_vectorcall_offset`** for details.

Inheritance:

This bit is inherited for types with the **`Py_TPFLAGS_IMMUTABLETYPE`** flag set, if **`tp_call`** is

also inherited.

New in version 3.9.

Py_TPFLAGS_IMMUTABLETYPE

This bit is set for type objects that are immutable: type attributes cannot be set nor deleted.

PyType_Ready() automatically applies this flag to static types.

Inheritance:

This flag is not inherited.

New in version 3.10.

Py_TPFLAGS_DISALLOW_INSTANTIATION

Disallow creating instances of the type: set **tp_new** to NULL and don't create the `__new__` key in the type dictionary.

The flag must be set before creating the type, not after. For example, it must be set before **PyType_Ready()** is called on the type.

The flag is set automatically on static types if **tp_base** is NULL or `&PyBaseObject_Type` and **tp_new** is NULL.

Inheritance:

This flag is not inherited. However, subclasses will not be instantiable unless they provide a non-NULL **tp_new** (which is only possible via the C API).

Note

To disallow instantiating a class directly but allow instantiating its subclasses (e.g. for an abstract base class), do not use this flag. Instead, make **tp_new**

only succeed for subclasses.

New in version 3.10.

Py_TPFLAGS_MAPPING

This bit indicates that instances of the class may match mapping patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Mapping`, and unset when registering `collections.abc.Sequence`.

Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_SEQUENCE`.

See also

PEP 634 [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

New in version 3.10.

Py_TPFLAGS_SEQUENCE

This bit indicates that instances of the class may match sequence patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Sequence`, and unset when registering `collections.abc.Mapping`.

Note

`Py_TPFLAGS_MAPPING` and

Py_TPFLAGS_SEQUENCE are mutually exclusive; it is an error to enable both flags simultaneously.

Inheritance:

This flag is inherited by types that do not already set **Py_TPFLAGS_MAPPING**.

See also

PEP 634 [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

New in version 3.10.

const char *PyTypeObject.tp_doc

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the **__doc__** attribute on the type and instances of the type.

Inheritance:

This field is *not* inherited by subtypes.

traverseproc PyTypeObject.tp_traverse

An optional pointer to a traversal function for the garbage collector. This is only used if the **Py_TPFLAGS_HAVE_GC** flag bit is set. The signature is:

```
int tp_traverse(PyObject *self, visitproc visit, vo
```

More information about Python's garbage collection scheme can be found in section Supporting Cyclic Garbage Collection.

The **tp_traverse** pointer is used by the garbage collector to detect reference cycles. A typical implementation of a **tp_traverse** function simply calls **Py_VISIT()** on each of the instance's members that are Python objects that the instance owns. For example, this is function **local_traverse()** from the **_thread** extension module:

```
static int
local_traverse(localobject *self, visitproc visit,
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that **`Py_VISIT()`** is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the **`gc`** module's **`get_referents()`** function will include it.

Warning

When implementing **`tp_traverse`**, only the members that the instance *owns* (by having strong references to them) must be visited. For instance, if an object supports weak references via the **`tp_weaklist`** slot, the pointer supporting the linked list (what *tp_weaklist* points to) must **not** be visited as the instance does not directly own the weak references to itself (the weakreference list is there to support the weak reference machinery, but the instance has no strong reference to the elements inside it, as they are allowed to be removed even if the instance is still alive).

Note that **`Py_VISIT()`** requires the *visit* and *arg* parameters to **`local_traverse()`** to have these specific names; don't name them just anything.

Instances of heap-allocated types hold a reference to their type. Their traversal function must therefore either visit **`Py_TYPE(self)`**, or delegate this responsibility by calling

`tp_traverse` of another heap-allocated type (such as a heap-allocated superclass). If they do not, the type object may not be garbage-collected.

Changed in version 3.9: Heap-allocated types are expected to visit `Py_TYPE(self)` in `tp_traverse`. In earlier versions of Python, due to bug 40217 [https://bugs.python.org/issue40217], doing this may lead to crashes in subclasses.

Inheritance:

Group: **`Py_TPFLAGS_HAVE_GC`**, **`tp_traverse`**, **`tp_clear`**

This field is inherited by subtypes together with **`tp_clear`** and the **`Py_TPFLAGS_HAVE_GC`** flag bit: the flag bit, **`tp_traverse`**, and **`tp_clear`** are all inherited from the base type if they are all zero in the subtype.

inquiry PyTypeObject.tp_clear

An optional pointer to a clear function for the garbage collector. This is only used if the **`Py_TPFLAGS_HAVE_GC`** flag bit is set. The signature is:

```
int tp_clear(PyObject *);
```

The **`tp_clear`** member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all **`tp_clear`** functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a **`tp_clear`** function. For example, the tuple type does not implement a **`tp_clear`** function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the **`tp_clear`** functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing **`tp_clear`**.

Implementations of **`tp_clear`** should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The **`Py_CLEAR()`** macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to `NULL`. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference *self* again, it's important that the pointer to the contained object be `NULL` at that time, so that *self* knows the contained object can no longer be used. The **`Py_CLEAR()`** macro performs the operations in a safe order.

Note that **`tp_clear`** is not *always* called before an instance is deallocated. For example, when reference counting is enough to determine that an object is no longer used, the cyclic garbage collector is not involved and **`tp_dealloc`** is called directly.

Because the goal of **`tp_clear`** functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's **`tp_dealloc`** function to invoke **`tp_clear`**.

More information about Python's garbage collection scheme can be found in section Supporting Cyclic Garbage Collection.

Inheritance:

Group: **Py_TPFLAGS_HAVE_GC**, **tp_traverse**, **tp_clear**

This field is inherited by subtypes together with **tp_traverse** and the **Py_TPFLAGS_HAVE_GC** flag bit: the flag bit, **tp_traverse**, and **tp_clear** are all inherited from the base type if they are all zero in the subtype.

richcmpfunc PyTypeObject.tp_richcompare

An optional pointer to the rich comparison function, whose signature is:

```
PyObject *tp_richcompare(PyObject *self, PyObject *
```

The first parameter is guaranteed to be an instance of the type that is defined by **PyTypeObject**.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

The following constants are defined to be used as the third argument for **tp_richcompare** and for **PyObject_RichCompare()**:

Constant	Comparison
Py_LT	
Py_LE	
Py_EQ	
Py_NE	
Py_GT	
Py_GE	

The following macro is defined to ease writing rich comparison functions:

Py_RETURN_RICHCOMPARE(VAL_A, VAL_B, op)

Return `Py_True` or `Py_False` from the function,

depending on the result of a comparison. VAL_A and VAL_B must be orderable by C comparison operators (for example, they may be C ints or floats). The third argument specifies the requested operation, as for **PyObject_RichCompare()**.

The return value's reference count is properly incremented.

On error, sets an exception and returns `NULL` from the function.

New in version 3.7.

Inheritance:

Group: **tp_hash**, **tp_richcompare**

This field is inherited by subtypes together with **tp_hash**: a subtype inherits **tp_richcompare** and **tp_hash** when the subtype's **tp_richcompare** and **tp_hash** are both `NULL`.

Default:

PyBaseObject_Type provides a **tp_richcompare** implementation, which may be inherited. However, if only **tp_hash** is defined, not even the inherited function is used and instances of the type will not be able to participate in any comparisons.

Py_ssize_t PyTypeObject.tp_weaklistoffset

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by **PyObject_ClearWeakRefs()** and the `PyWeakref_*` functions. The instance structure needs to include a field of type PyObject* which is initialized to `NULL`.

Do not confuse this field with **tp_weaklist**; that is the list head for weak references to the type object itself.

Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via **tp_weaklistoffset**, this should not be a problem.

When a type defined by a class statement has no **__slots__** declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the **tp_weaklistoffset** of that slot's offset.

When a type's **__slots__** declaration contains a slot named **__weakref__**, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's **tp_weaklistoffset**.

When a type's **__slots__** declaration does not contain a slot named **__weakref__**, the type inherits its **tp_weaklistoffset** from its base type.

getiterfunc PyTypeObject.tp_iter

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function).

This function has the same signature as **PyObject_GetIter()**:

```
PyObject *tp_iter(PyObject *self);
```

Inheritance:

This field is inherited by subtypes.

iternextfunc PyTypeObject.tp_iternext

An optional pointer to a function that returns the next item in an iterator. The signature is:

```
PyObject *tp_iternext(PyObject *self);
```

When the iterator is exhausted, it must return `NULL`; a **`StopIteration`** exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the **`tp_iter`** function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as **`PyIter_Next()`**.

Inheritance:

This field is inherited by subtypes.

struct PyMethodDef *PyTypeObject.tp_methods

An optional pointer to a static `NULL`-terminated array of **`PyMethodDef`** structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see **`tp_dict`** below) containing a method descriptor.

Inheritance:

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct PyMemberDef *PyTypeObject.tp_members

An optional pointer to a static `NULL`-terminated array of **`PyMemberDef`** structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see **`tp_dict`** below) containing a member descriptor.

Inheritance:

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct PyGetSetDef *PyTypeObject.tp_getset

An optional pointer to a static `NULL`-terminated array of **`PyGetSetDef`** structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see **`tp_dict`** below) containing a getset descriptor.

Inheritance:

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

PyTypeObject *PyTypeObject.tp_base

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

Note

Slot initialization is subject to the rules of initializing globals. C99 requires the initializers to be "address constants". Function designators like **`PyType_GenericNew()`**, with implicit conversion to a pointer, are valid C99 address constants.

However, the unary '&' operator applied to a non-static variable like **`PyBaseObject_Type()`** is not required to produce an address constant. Compilers may support this (gcc does), MSVC does not. Both compilers are strictly standard conforming in this particular behavior.

Consequently, **`tp_base`** should be set in the extension module's init function.

Inheritance:

This field is not inherited by subtypes (obviously).

Default:

This field defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type **`object`**).

PyObject *PyTypeObject.tp_dict

The type's dictionary is stored here by **`PyType_Ready()`**.

This field should normally be initialized to `NULL` before PyType_Ready is called; it may also be initialized to a dictionary containing initial attributes for the type. Once **`PyType_Ready()`** has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like **`__add__()`**).

Inheritance:

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

Default:

If this field is `NULL`, **`PyType_Ready()`** will assign a new dictionary to it.

Warning

It is not safe to use **`PyDict_SetItem()`** on or otherwise modify **`tp_dict`** with the dictionary C-API.

descrgetfunc PyTypeObject.tp_descr_get

An optional pointer to a "descriptor get" function.

The function signature is:

```
PyObject * tp_descr_get(PyObject *self, PyObject *o
```

Inheritance:

This field is inherited by subtypes.

descrsetfunc PyTypeObject.tp_descr_set

An optional pointer to a function for setting and deleting a descriptor's value.

The function signature is:

```
int tp_descr_set(PyObject *self, PyObject *obj, PyO
```

The *value* argument is set to `NULL` to delete the value.

Inheritance:

This field is inherited by subtypes.

Py_ssize_t PyTypeObject.tp_dictoffset

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by **`PyObject_GenericGetAttr()`**.

Do not confuse this field with **`tp_dict`**; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the *end* of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of **`str`** or **`tuple`**. Note that the **`tp_basicsize`** field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, **`tp_dictoffset`** should be set to `-4` to indicate that the dictionary is at the very end of the structure.

The **tp_dictoffset** should be regarded as write-only. To get the pointer to the dictionary call **PyObject_GenericGetDict()**. Calling **PyObject_GenericGetDict()** may need to allocate memory for the dictionary, so it is may be more efficient to call **PyObject_GetAttr()** when accessing an attribute on the object.

Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via **tp_dictoffset**, this should not be a problem.

When a type defined by a class statement has no **__slots__** declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the **tp_dictoffset** is set to that slot's offset.

When a type defined by a class statement has a **__slots__** declaration, the type inherits its **tp_dictoffset** from its base type.

(Adding a slot named **__dict__** to the **__slots__** declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like **__weakref__** though.)

Default:

This slot has no default. For static types, if the field is `NULL` then no **__dict__** gets created for instances.

initproc PyTypeObject.tp_init

An optional pointer to an instance initialization function.

This function corresponds to the **__init__()** method of classes. Like **__init__()**, it is possible to create an instance without calling **__init__()**, and it is possible to reinitialize

an instance by calling its **`__init__()`** method again.

The function signature is:

```
int tp_init(PyObject *self, PyObject *args, PyObjec
```

The self argument is the instance to be initialized; the *args* and *kwds* arguments represent positional and keyword arguments of the call to **`__init__()`**.

The **`tp_init`** function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's **`tp_new`** function has returned an instance of the type. If the **`tp_new`** function returns an instance of some other type that is not a subtype of the original type, no **`tp_init`** function is called; if **`tp_new`** returns an instance of a subtype of the original type, the subtype's **`tp_init`** is called.

Returns `0` on success, `-1` and sets an exception on error.

Inheritance:

This field is inherited by subtypes.

Default:

For static types this field does not have a default.

allocfunc PyTypeObject.tp_alloc

An optional pointer to an instance allocation function.

The function signature is:

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t n
```

Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement).

Default:

For dynamic subtypes, this field is always set to **PyType_GenericAlloc()**, to force a standard heap allocation strategy.

For static subtypes, **PyBaseObject_Type** uses **PyType_GenericAlloc()**. That is the recommended value for all statically defined types.

newfunc PyTypeObject.tp_new

An optional pointer to an instance creation function.

The function signature is:

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *a
```

The *subtype* argument is the type of the object being created; the *args* and *kwds* arguments represent positional and keyword arguments of the call to the type. Note that *subtype* doesn't have to equal the type whose **tp_new** function is called; it may be a subtype of that type (but not an unrelated type).

The **tp_new** function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the **tp_init** handler. A good rule of thumb is that for immutable types, all initialization should take place in **tp_new**, while for mutable types, most initialization should be deferred to **tp_init**.

Set the **Py_TPFLAGS_DISALLOW_INSTANTIATION** flag to disallow creating instances of the type in Python.

Inheritance:

This field is inherited by subtypes, except it is not inherited by static types whose **tp_base** is `NULL` or `&PyBaseObject_Type`.

Default:

For static types this field has no default. This means if the slot is defined as `NULL`, the type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

freefunc PyTypeObject.tp_free

An optional pointer to an instance deallocation function. Its signature is:

```
void tp_free(void *self);
```

An initializer that is compatible with this signature is **`PyObject_Free()`**.

Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement)

Default:

In dynamic subtypes, this field is set to a deallocator suitable to match **`PyType_GenericAlloc()`** and the value of the **`Py_TPFLAGS_HAVE_GC`** flag bit.

For static subtypes, **`PyBaseObject_Type`** uses PyObject_Del.

inquiry PyTypeObject.tp_is_gc

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's **`tp_flags`** field, and check the **`Py_TPFLAGS_HAVE_GC`** flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is:

```
int tp_is_gc(PyObject *self);
```

(The only example of this are types themselves. The metatype, **PyType_Type**, defines this function to distinguish between statically and dynamically allocated types.)

Inheritance:

This field is inherited by subtypes.

Default:

This slot has no default. If this field is `NULL`, **Py_TPFLAGS_HAVE_GC** is used as the functional equivalent.

PyObject *PyTypeObject.tp_bases

Tuple of base types.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **initialized**.

For dynamically created classes, the `Py_tp_bases` **slot** can be used instead of the *bases* argument of **PyType_FromSpecWithBases()**. The argument form is preferred.

Warning

Multiple inheritance does not work well for statically defined types. If you set `tp_bases` to a tuple, Python will not raise an error, but some slots will only be inherited from the first base.

Inheritance:

This field is not inherited.

PyObject *PyTypeObject.tp_mro

Tuple containing the expanded set of base types, starting with the type itself and ending with **object**, in Method

Resolution Order.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **`initialized`**.

Inheritance:

This field is not inherited; it is calculated fresh by **`PyType_Ready()`**.

PyObject *PyTypeObject.tp_cache

Unused. Internal use only.

Inheritance:

This field is not inherited.

PyObject *PyTypeObject.tp_subclasses

List of weak references to subclasses. Internal use only.

Inheritance:

This field is not inherited.

PyObject *PyTypeObject.tp_weaklist

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

Inheritance:

This field is not inherited.

destructor PyTypeObject.tp_del

This field is deprecated. Use **`tp_finalize`** instead.

unsigned int PyTypeObject.tp_version_tag

Used to index into the method cache. Internal use only.

Inheritance:

This field is not inherited.

destructor PyTypeObject.tp_finalize

An optional pointer to an instance finalization function. Its signature is:

```
void tp_finalize(PyObject *self);
```

If **tp_finalize** is set, the interpreter calls it once when finalizing an instance. It is called either from the garbage collector (if the instance is part of an isolated reference cycle) or just before the object is deallocated. Either way, it is guaranteed to be called before attempting to break reference cycles, ensuring that it finds the object in a sane state.

tp_finalize should not mutate the current exception status; therefore, a recommended way to write a non-trivial finalizer is:

```
static void
local_finalize(PyObject *self)
{
    PyObject *error_type, *error_value, *error_trac

    /* Save the current exception, if any. */
    PyErr_Fetch(&error_type, &error_value, &error_t

    /* ... */

    /* Restore the saved exception. */
    PyErr_Restore(error_type, error_value, error_tr
}
```

Also, note that, in a garbage collected Python, **tp_dealloc** may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which tp_dealloc is called will own the Global Interpreter Lock (GIL). However, if the object

being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called tp_dealloc will not violate any assumptions of the library.

Inheritance:

This field is inherited by subtypes.

New in version 3.4.

Changed in version 3.8: Before version 3.8 it was necessary to set the **Py_TPFLAGS_HAVE_FINALIZE** flags bit in order for this field to be used. This is no longer required.

See also

"Safe object finalization" (**PEP 442** [https://peps.python.org/pep-0442/])

vectorcallfunc PyTypeObject.tp_vectorcall

Vectorcall function to use for calls of this type object. In other words, it is used to implement vectorcall for `type.__call__`. If `tp_vectorcall` is `NULL`, the default call implementation using **__new__** and **__init__** is used.

Inheritance:

This field is never inherited.

New in version 3.9: (the field exists since 3.8 but it's only used since 3.9)

Static Types

Traditionally, types defined in C code are *static*, that is, a static **PyTypeObject** structure is defined directly in code and initialized using **PyType_Ready()**.

This results in types that are limited relative to types defined in Python:

- Static types are limited to one base, i.e. they cannot use multiple inheritance.
- Static type objects (but not necessarily their instances) are immutable. It is not possible to add or modify the type object's attributes from Python.
- Static type objects are shared across sub-interpreters, so they should not include any subinterpreter-specific state.

Also, since **PyTypeObject** is only part of the Limited API as an opaque struct, any extension modules using static types must be compiled for a specific Python minor version.

Heap Types

An alternative to static types is *heap-allocated types*, or *heap types* for short, which correspond closely to classes created by Python's `class` statement. Heap types have the **Py_TPFLAGS_HEAPTYPE** flag set.

This is done by filling a **PyType_Spec** structure and calling **PyType_FromSpec()**, **PyType_FromSpecWithBases()**, or **PyType_FromModuleAndSpec()**.

Number Object Structures

type PyNumberMethods

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the Number Protocol section.

Here is the structure definition:

```
typedef struct {
```

```
binaryfunc nb_add;
binaryfunc nb_subtract;
binaryfunc nb_multiply;
binaryfunc nb_remainder;
binaryfunc nb_divmod;
ternaryfunc nb_power;
unaryfunc nb_negative;
unaryfunc nb_positive;
unaryfunc nb_absolute;
inquiry nb_bool;
unaryfunc nb_invert;
binaryfunc nb_lshift;
binaryfunc nb_rshift;
binaryfunc nb_and;
binaryfunc nb_xor;
binaryfunc nb_or;
unaryfunc nb_int;
void *nb_reserved;
unaryfunc nb_float;

binaryfunc nb_inplace_add;
binaryfunc nb_inplace_subtract;
binaryfunc nb_inplace_multiply;
binaryfunc nb_inplace_remainder;
ternaryfunc nb_inplace_power;
binaryfunc nb_inplace_lshift;
binaryfunc nb_inplace_rshift;
binaryfunc nb_inplace_and;
binaryfunc nb_inplace_xor;
binaryfunc nb_inplace_or;

binaryfunc nb_floor_divide;
binaryfunc nb_true_divide;
binaryfunc nb_inplace_floor_divide;
binaryfunc nb_inplace_true_divide;

unaryfunc nb_index;
```

```
    binaryfunc nb_matrix_multiply;
    binaryfunc nb_inplace_matrix_multiply;
} PyNumberMethods;
```

Note

Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return `Py_NotImplemented`, if another error occurred they must return `NULL` and set an exception.

Note

The **`nb_reserved`** field should always be `NULL`. It was previously called **`nb_long`**, and was renamed in Python 3.0.1.

binaryfunc PyNumberMethods.nb_add

binaryfunc PyNumberMethods.nb_subtract

binaryfunc PyNumberMethods.nb_multiply

binaryfunc PyNumberMethods.nb_remainder

binaryfunc PyNumberMethods.nb_divmod

binaryfunc PyNumberMethods.nb_matrix_multiply

binaryfunc PyNumberMethods.nb_inplace_matrix_multiply

Mapping Object Structures

type PyMappingMethods

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

lenfunc PyMappingMethods.mp_length

This function is used by **`PyMapping_Size()`** and **`PyObject_Size()`**, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

binaryfunc PyMappingMethods.mp_subscript

This function is used by **`PyObject_GetItem()`** and **`PySequence_GetSlice()`**, and has the same signature as **`PyObject_GetItem()`**. This slot must be filled for the **`PyMapping_Check()`** function to return `1`, it can be `NULL` otherwise.

objobjargproc PyMappingMethods.mp_ass_subscript

This function is used by **PyObject_SetItem()**, **PyObject_DelItem()**, **PyObject_SetSlice()** and **PyObject_DelSlice()**. It has the same signature as **PyObject_SetItem()**, but *v* can also be set to NULL to delete an item. If this slot is NULL, the object does not support item assignment and deletion.

Sequence Object Structures

type PySequenceMethods

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

lenfunc PySequenceMethods.sq_length

This function is used by **PySequence_Size()** and **PyObject_Size()**, and has the same signature. It is also used for handling negative indices via the **sq_item** and the **sq_ass_item** slots.

binaryfunc PySequenceMethods.sq_concat

This function is used by **PySequence_Concat()** and has the same signature. It is also used by the + operator, after trying the numeric addition via the **nb_add** slot.

ssizeargfunc PySequenceMethods.sq_repeat

This function is used by **PySequence_Repeat()** and has the same signature. It is also used by the * operator, after trying numeric multiplication via the **nb_multiply** slot.

ssizeargfunc PySequenceMethods.sq_item

This function is used by **PySequence_GetItem()** and has the same signature. It is also used by **PyObject_GetItem()**, after trying the subscription via the **mp_subscript** slot. This slot must be filled for the

PySequence_Check() function to return `1`, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the **sq_length** slot is filled, it is called and the sequence length is used to compute a positive index which is passed to **sq_item**. If **sq_length** is `NULL`, the index is passed as is to the function.

ssizeobjargproc PySequenceMethods.sq_ass_item

This function is used by **PySequence_SetItem()** and has the same signature. It is also used by **PyObject_SetItem()** and **PyObject_DelItem()**, after trying the item assignment and deletion via the **mp_ass_subscript** slot. This slot may be left to `NULL` if the object does not support item assignment and deletion.

objobjproc PySequenceMethods.sq_contains

This function may be used by **PySequence_Contains()** and has the same signature. This slot may be left to `NULL`, in this case **PySequence_Contains()** simply traverses the sequence until it finds a match.

binaryfunc PySequenceMethods.sq_inplace_concat

This function is used by **PySequence_InPlaceConcat()** and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case **PySequence_InPlaceConcat()** will fall back to **PySequence_Concat()**. It is also used by the augmented assignment `+=`, after trying numeric in-place addition via the **nb_inplace_add** slot.

ssizeargfunc PySequenceMethods.sq_inplace_repeat

This function is used by **PySequence_InPlaceRepeat()** and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case **PySequence_InPlaceRepeat()** will fall back to **PySequence_Repeat()**. It is also used by the augmented assignment `*=`, after trying numeric in-place multiplication via the **nb_inplace_multiply** slot.

Buffer Object Structures

type PyBufferProcs

This structure holds pointers to the functions required by the Buffer protocol. The protocol defines how an exporter object can expose its internal data to consumer objects.

getbufferproc PyBufferProcs.bf_getbuffer

The signature of this function is:

```
int (PyObject *exporter, Py_buffer *view, int flags
```

Handle a request to *exporter* to fill in *view* as specified by *flags*. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise **`PyExc_BufferError`**, set view->obj to `NULL` and return `-1`.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set view->obj to *exporter* and increment view->obj.
5. Return `0`.

If *exporter* is part of a chain or tree of buffer providers, two main schemes can be used:

- Re-export: Each member of the tree acts as the exporting object and sets view->obj to a new reference to itself.
- Redirect: The buffer request is redirected to the root object of the tree. Here, view->obj will be a new reference to the root object.

The individual fields of *view* are described in section Buffer structure, the rules how an exporter must react to specific

requests are in section Buffer request types.

All memory pointed to in the **`Py_buffer`** structure belongs to the exporter and must remain valid until there are no consumers left. **`format`**, **`shape`**, **`strides`**, **`suboffsets`** and **`internal`** are read-only for the consumer.

`PyBuffer_FillInfo()` provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

`PyObject_GetBuffer()` is the interface for the consumer that wraps this function.

releasebufferproc PyBufferProcs.bf_releasebuffer

The signature of this function is:

```
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released, **`PyBufferProcs.bf_releasebuffer`** may be `NULL`. Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is `0`, free all memory associated with *view*.

The exporter MUST use the **`internal`** field to keep track of buffer-specific resources. This field is guaranteed to remain constant, while a consumer MAY pass a copy of the original buffer as the *view* argument.

This function MUST NOT decrement view->obj, since that is done automatically in **`PyBuffer_Release()`** (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.

Async Object Structures

New in version 3.5.

type PyAsyncMethods

This structure holds pointers to the functions required to implement awaitable and asynchronous iterator objects.

Here is the structure definition:

```
typedef struct {
    unaryfunc am_await;
    unaryfunc am_aiter;
    unaryfunc am_anext;
    sendfunc am_send;
} PyAsyncMethods;
```

unaryfunc PyAsyncMethods.am_await

The signature of this function is:

```
PyObject *am_await(PyObject *self);
```

The returned object must be an iterator, i.e. **`PyIter_Check()`** must return `1` for it.

This slot may be set to `NULL` if an object is not an awaitable.

unaryfunc PyAsyncMethods.am_aiter

The signature of this function is:

```
PyObject *am_aiter(PyObject *self);
```

Must return an asynchronous iterator object. See **`__anext__()`** for details.

This slot may be set to `NULL` if an object does not implement asynchronous iteration protocol.

unaryfunc PyAsyncMethods.am_anext

The signature of this function is:

```
PyObject *am_anext(PyObject *self);
```

Must return an awaitable object. See **`__anext__()`** for details. This slot may be set to `NULL`.

sendfunc PyAsyncMethods.am_send

The signature of this function is:

```
PySendResult am_send(PyObject *self, PyObject *arg,
```

See **`PyIter_Send()`** for details. This slot may be set to `NULL`.

New in version 3.10.

Slot Type typedefs

typedef PyObject *(*allocfunc)(PyTypeObject *cls, Py_ssize_t nitems)

Part of the Stable ABI.
The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with **`ob_refcnt`** set to `1` and **`ob_type`** set to the type argument. If the type's **`tp_itemsize`** is non-zero, the object's **`ob_size`** field should be initialized to *nitems* and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, *nitems* is not used and the length of the block should be **`tp_basicsize`**.

This function should not do any other instance initialization, not even to allocate additional memory; that should be done

by **tp_new**.

typedef void (*destructor)(PyObject*)
Part of the Stable ABI.

typedef void (*freefunc)(void*)
See **tp_free**.

typedef PyObject *(*newfunc)(PyObject*, PyObject*, PyObject*)
Part of the Stable ABI.
See **tp_new**.

typedef int (*initproc)(PyObject*, PyObject*, PyObject*)
Part of the Stable ABI.
See **tp_init**.

typedef PyObject *(*reprfunc)(PyObject*)
Part of the Stable ABI.
See **tp_repr**.

typedef PyObject *(*getattrfunc)(PyObject *self, char *attr)
Part of the Stable ABI.
Return the value of the named attribute for the object.

typedef int (*setattrfunc)(PyObject *self, char *attr, PyObject *value)
Part of the Stable ABI.
Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

typedef PyObject *(*getattrofunc)(PyObject *self, PyObject *attr)
Part of the Stable ABI.
Return the value of the named attribute for the object.

See **tp_getattro**.

typedef int (*setattrofunc)(PyObject *self, PyObject *attr, PyObject

*value)

Part of the Stable ABI.
Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

See **tp_setattro**.

typedef PyObject *(*descrgetfunc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **tp_descr_get**.

typedef int (*descrsetfunc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **tp_descr_set**.

typedef Py_hash_t (*hashfunc)(PyObject*)

Part of the Stable ABI.
See **tp_hash**.

typedef PyObject *(*richcmpfunc)(PyObject*, PyObject*, int)

Part of the Stable ABI.
See **tp_richcompare**.

typedef PyObject *(*getiterfunc)(PyObject*)

Part of the Stable ABI.
See **tp_iter**.

typedef PyObject *(*iternextfunc)(PyObject*)

Part of the Stable ABI.
See **tp_iternext**.

typedef Py_ssize_t (*lenfunc)(PyObject*)

Part of the Stable ABI.

typedef int (*getbufferproc)(PyObject*, Py_buffer*, int)

typedef void (*releasebufferproc)(PyObject*, Py_buffer*)

typedef PyObject *(*unaryfunc)(PyObject*)
Part of the Stable ABI.

typedef PyObject *(*binaryfunc)(PyObject*, PyObject*)
Part of the Stable ABI.

typedef PySendResult (*sendfunc)(PyObject*, PyObject*, PyObject**)
See **am_send**.

typedef PyObject *(*ternaryfunc)(PyObject*, PyObject*, PyObject*)
Part of the Stable ABI.

typedef PyObject *(*ssizeargfunc)(PyObject*, Py_ssize_t)
Part of the Stable ABI.

typedef int (*ssizeobjargproc)(PyObject*, Py_ssize_t)
Part of the Stable ABI.

typedef int (*objobjproc)(PyObject*, PyObject*)
Part of the Stable ABI.

typedef int (*objobjargproc)(PyObject*, PyObject*, PyObject*)
Part of the Stable ABI.

Examples

The following are simple examples of Python type definitions. They include common usage you may encounter. Some demonstrate tricky corner cases. For more examples, practical info, and a tutorial, see Defining Extension Types: Tutorial and Defining Extension Types: Assorted Topics.

A basic static type:

```
typedef struct {
    PyObject_HEAD
    const char *data;
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_new = myobj_new,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
};
```

You may also find older code (especially in the CPython code base) with a more verbose initializer:

```
static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "mymod.MyObject",               /* tp_name */
    sizeof(MyObject),               /* tp_basicsize */
    0,                              /* tp_itemsize */
    (destructor)myobj_dealloc,      /* tp_dealloc */
    0,                              /* tp_vectorcall_off
    0,                              /* tp_getattr */
    0,                              /* tp_setattr */
    0,                              /* tp_as_async */
    (reprfunc)myobj_repr,           /* tp_repr */
    0,                              /* tp_as_number */
    0,                              /* tp_as_sequence */
    0,                              /* tp_as_mapping */
    0,                              /* tp_hash */
    0,                              /* tp_call */
    0,                              /* tp_str */
    0,                              /* tp_getattro */
    0,                              /* tp_setattro */
```

```
    0,                                  /* tp_as_buffer */
    0,                                  /* tp_flags */
    PyDoc_STR("My objects"),            /* tp_doc */
    0,                                  /* tp_traverse */
    0,                                  /* tp_clear */
    0,                                  /* tp_richcompare */
    0,                                  /* tp_weaklistoffset
    0,                                  /* tp_iter */
    0,                                  /* tp_iternext */
    0,                                  /* tp_methods */
    0,                                  /* tp_members */
    0,                                  /* tp_getset */
    0,                                  /* tp_base */
    0,                                  /* tp_dict */
    0,                                  /* tp_descr_get */
    0,                                  /* tp_descr_set */
    0,                                  /* tp_dictoffset */
    0,                                  /* tp_init */
    0,                                  /* tp_alloc */
    myobj_new,                          /* tp_new */
};
```

A type that supports weakrefs, instance dicts, and hashing:

```
typedef struct {
    PyObject_HEAD
    const char *data;
    PyObject *inst_dict;
    PyObject *weakreflist;
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_weaklistoffset = offsetof(MyObject, weakreflist)
    .tp_dictoffset = offsetof(MyObject, inst_dict),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE
```

```
    .tp_new = myobj_new,
    .tp_traverse = (traverseproc)myobj_traverse,
    .tp_clear = (inquiry)myobj_clear,
    .tp_alloc = PyType_GenericNew,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
    .tp_hash = (hashfunc)myobj_hash,
    .tp_richcompare = PyBaseObject_Type.tp_richcompare,
};
```

A str subclass that cannot be subclassed and cannot be called to create instances (e.g. uses a separate factory func) using **`Py_TPFLAGS_DISALLOW_INSTANTIATION`** flag:

```
typedef struct {
    PyUnicodeObject raw;
    char *extra;
} MyStr;

static PyTypeObject MyStr_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyStr",
    .tp_basicsize = sizeof(MyStr),
    .tp_base = NULL,  // set to &PyUnicode_Type in modul
    .tp_doc = PyDoc_STR("my custom str"),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_DISALLOW
    .tp_repr = (reprfunc)myobj_repr,
};
```

The simplest static type with fixed-length instances:

```
typedef struct {
    PyObject_HEAD
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
};
```

The simplest static type with variable-length instances:

```
typedef struct {
    PyObject_VAR_HEAD
    const char *data[1];
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject) - sizeof(char *),
    .tp_itemsize = sizeof(char *),
};
```

Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

Py_TPFLAGS_HAVE_GC

> Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.

2. The object's memory must be deallocated using **PyObject_GC_Del()**.

   Warning

   If a type adds the Py_TPFLAGS_HAVE_GC, then it *must* implement at least a **tp_traverse** handler or explicitly use one from its subclass or subclasses.

   When calling **PyType_Ready()** or some of the APIs that indirectly call it like **PyType_FromSpecWithBases()** or **PyType_FromSpec()** the interpreter will automatically populate the **tp_flags**, **tp_traverse** and **tp_clear** fields if the type inherits from a class that implements the garbage collector protocol and the child class does *not* include the **Py_TPFLAGS_HAVE_GC** flag.

TYPE *PyObject_GC_New(TYPE, PyTypeObject *type)

Analogous to **PyObject_New()** but for container objects with the **Py_TPFLAGS_HAVE_GC** flag set.

TYPE *PyObject_GC_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)

Analogous to **PyObject_NewVar()** but for container objects with the **Py_TPFLAGS_HAVE_GC** flag set.

TYPE *PyObject_GC_Resize(TYPE, PyVarObject *op, Py_ssize_t newsize)

Resize an object allocated by **PyObject_NewVar()**. Returns the resized object or `NULL` on failure. *op* must not be tracked by the collector yet.

void PyObject_GC_Track(PyObject *op)

Part of the Stable ABI.
Adds the object *op* to the set of container objects tracked by the collector. The collector can run at unexpected times so

objects must be valid while being tracked. This should be called once all the fields followed by the **tp_traverse** handler become valid, usually near the end of the constructor.

int PyObject_IS_GC(PyObject *obj)

Returns non-zero if the object implements the garbage collector protocol, otherwise returns 0.

The object cannot be tracked by the garbage collector if this function returns 0.

int PyObject_GC_IsTracked(PyObject *op)

Part of the Stable ABI since version 3.9.
Returns 1 if the object type of *op* implements the GC protocol and *op* is being currently tracked by the garbage collector and 0 otherwise.

This is analogous to the Python function **gc.is_tracked()**.

New in version 3.9.

int PyObject_GC_IsFinalized(PyObject *op)

Part of the Stable ABI since version 3.9.
Returns 1 if the object type of *op* implements the GC protocol and *op* has been already finalized by the garbage collector and 0 otherwise.

This is analogous to the Python function **gc.is_finalized()**.

New in version 3.9.

void PyObject_GC_Del(void *op)

Part of the Stable ABI.
Releases memory allocated to an object using **PyObject_GC_New()** or **PyObject_GC_NewVar()**.

void PyObject_GC_UnTrack(void *op)

Part of the Stable ABI.
Remove the object *op* from the set of container objects tracked by the collector. Note that **PyObject_GC_Track()** can be called again on this object to add it back to the set of tracked objects. The deallocator (**tp_dealloc** handler) should call this for the object before any of the fields used by the **tp_traverse** handler become invalid.

Changed in version 3.8: The **_PyObject_GC_TRACK()** and **_PyObject_GC_UNTRACK()** macros have been removed from the public C API.

The **tp_traverse** handler accepts a function parameter of this type:

typedef int (*visitproc)(PyObject *object, void *arg)

Part of the Stable ABI.
Type of the visitor function passed to the **tp_traverse** handler. The function should be called with an object to traverse as *object* and the third parameter to the **tp_traverse** handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The **tp_traverse** handler must have the following type:

typedef int (*traverseproc)(PyObject *self, visitproc visit, void *arg)

Part of the Stable ABI.
Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a `NULL` object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing **tp_traverse** handlers, a **Py_VISIT()**

macro is provided. In order to use this macro, the **tp_traverse** implementation must name its arguments exactly *visit* and *arg*:

void Py_VISIT(PyObject *o)

If *o* is not `NULL`, call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, **tp_traverse** handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The **tp_clear** handler must be of the **inquiry** type, or `NULL` if the object is immutable.

typedef int (*inquiry)(PyObject *self)

Part of the Stable ABI.
Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call **Py_DECREF()** on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

Controlling the Garbage Collector State

The C-API provides the following functions for controlling garbage collection runs.

Py_ssize_t PyGC_Collect(void)

Part of the Stable ABI.
Perform a full garbage collection, if the garbage collector is enabled. (Note that **gc.collect()** runs it unconditionally.)

Returns the number of collected + unreachable objects which cannot be collected. If the garbage collector is disabled or already collecting, returns `0` immediately. Errors during garbage collection are passed to **`sys.unraisablehook`**. This function does not raise exceptions.

int PyGC_Enable(void)

Part of the Stable ABI since version 3.10.
Enable the garbage collector: similar to **`gc.enable()`**. Returns the previous state, 0 for disabled and 1 for enabled.

New in version 3.10.

int PyGC_Disable(void)

Part of the Stable ABI since version 3.10.
Disable the garbage collector: similar to **`gc.disable()`**. Returns the previous state, 0 for disabled and 1 for enabled.

New in version 3.10.

int PyGC_IsEnabled(void)

Part of the Stable ABI since version 3.10.
Query the state of the garbage collector: similar to **`gc.isenabled()`**. Returns the current state, 0 for disabled and 1 for enabled.

New in version 3.10.

API and ABI Versioning

CPython exposes its version number in the following macros. Note that these correspond to the version code is **built** with, not necessarily the version used at **run time**.

See C API Stability for a discussion of API and ABI stability across versions.

PY_MAJOR_VERSION

The `3` in `3.4.1a2`.

PY_MINOR_VERSION

The `4` in `3.4.1a2`.

PY_MICRO_VERSION

The `1` in `3.4.1a2`.

PY_RELEASE_LEVEL

The `a` in `3.4.1a2`. This can be `0xA` for alpha, `0xB` for beta, `0xC` for release candidate or `0xF` for final.

PY_RELEASE_SERIAL

The `2` in `3.4.1a2`. Zero for final releases.

PY_VERSION_HEX

The Python version number encoded in a single integer.

The underlying version information can be found by treating it as a 32 bit number in the following manner:

Bytes (big endian order)	
1	PY_MAJOR_VERSION
2	PY_MINOR_VERSION
3	PY_MICRO_VERSION

25–28	PY_RELEASE_LEVEL
29–32	PY_RELEASE_SERIAL

Thus `3.4.1a2` is hexversion `0x030401a2` and `3.10.0` is hexversion `0x030a00f0`.

This version is also available via the symbol **`Py_Version`**.

const unsigned long Py_Version

Part of the Stable ABI since version 3.11.
The Python runtime version number encoded in a single constant integer, with the same format as the **`PY_VERSION_HEX`** macro. This contains the Python version used at run time.

New in version 3.11.

All the given macros are defined in Include/patchlevel.h [https://github.com/python/cpython/tree/3.11/Include/patchlevel.h].

Distributing Python Modules

Email

distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the distribution part of the process. For a guide to installing other Python projects, refer to the installation guide.

Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

Key terms

- the Python Package Index [https://pypi.org] is a public repository of open source licensed packages made available for use by other Python users
- the Python Packaging Authority [https://www.pypa.io/] are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards.

They maintain a variety of tools, documentation and issue trackers on both GitHub [https://github.com/pypa] and Bitbucket [https://bitbucket.org/pypa/].

- **`distutils`** is the original build and distribution system first added to the Python standard library in 1998. While direct use of **`distutils`** is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).
- setuptools [https://setuptools.readthedocs.io/en/latest/] is a (largely) drop-in replacement for **`distutils`** first published in 2004. Its most notable addition over the unmodified **`distutils`** tools was the ability to declare dependencies on other packages. It is currently recommended as a more regularly updated alternative to **`distutils`** that offers consistent support for more recent packaging standards across a wide range of Python versions.
- wheel [https://wheel.readthedocs.io/] (in this context) is a project that adds the `bdist_wheel` command to **`distutils`**/setuptools [https://setuptools.readthedocs.io/en/latest/]. This produces a cross platform binary packaging format (called "wheels" or "wheel files" and defined in **PEP 427** [https://peps.python.org/pep-0427/]) that allows Python libraries, even those including binary extensions, to be installed on a system without needing to be built locally.

Open source licensing and collaboration

In most parts of the world, software is automatically covered by copyright. This means that other developers require explicit permission to copy, use, modify and redistribute the software.

Open source licensing is a way of explicitly granting such permission in a relatively consistent way, allowing developers to share and collaborate efficiently by making common solutions to various problems freely available. This leaves many developers free to spend more time focusing on the problems that are relatively unique to their specific situation.

The distribution tools provided with Python are designed to make it reasonably straightforward for developers to make their own contributions back to that common pool of software if they choose to do so.

The same distribution tools can also be used to distribute software within an organisation, regardless of whether that software is published as open source software or not.

Installing the tools

The standard library does not include build tools that support modern Python packaging standards, as the core development team has found that it is important to have standard tools that work consistently, even on older versions of Python.

The currently recommended build and distribution tools can be installed by invoking the `pip` module at the command line:

```
python -m pip install setuptools wheel twine
```

Note

For POSIX users (including macOS and Linux users), these instructions assume the use of a virtual environment.

For Windows users, these instructions assume that the option to adjust the system PATH environment variable was selected when installing Python.

The Python Packaging User Guide includes more details on the currently recommended tools [https://packaging.python.org/guides/tool-recommendations/#packaging-tool-recommendations].

Reading the Python Packaging User Guide

The Python Packaging User Guide covers the various key steps and elements involved in creating and publishing a project:

- Project structure
- Building and packaging the project
- Uploading the project to the Python Package Index
- The .pypirc file

How do I…?

These are quick answers or links for some common tasks.

… choose a name for my project?

This isn't an easy topic, but here are a few tips:

- check the Python Package Index to see if the name is already in use
- check popular hosting sites like GitHub, Bitbucket, etc to see if there is already a project with that name
- check what comes up in a web search for the name you're considering
- avoid particularly common words, especially ones with multiple meanings, as they can make it difficult for users to find your software when searching for it

… create and distribute binary extensions?

This is actually quite a complex topic, with a variety of alternatives available depending on exactly what you're aiming to achieve. See the Python Packaging User Guide for more information and recommendations.

Installing Python Modules

Email

distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the distribution guide.

Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

Key terms

- `pip` is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.
- A *virtual environment* is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.
- `venv` is the standard tool for creating virtual environments,

and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing `pip` into all created virtual environments.

- `virtualenv` is a third party alternative (and predecessor) to `venv`. It allows virtual environments to be used on versions of Python prior to 3.4, which either don't provide `venv` at all, or aren't able to automatically install `pip` into created environments.
- The Python Package Index [https://pypi.org] is a public repository of open source licensed packages made available for use by other Python users.
- the Python Packaging Authority [https://www.pypa.io/] is the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation, and issue trackers on both GitHub [https://github.com/pypa] and Bitbucket [https://bitbucket.org/pypa/].
- `distutils` is the original build and distribution system first added to the Python standard library in 1998. While direct use of `distutils` is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).

Changed in version 3.5: The use of `venv` is now recommended for creating virtual environments.

Python Packaging User Guide: Creating and using virtual environments [https://packaging.python.org/installing/#creating-virtual-environments]

Basic usage

The standard packaging tools are all designed to be used from the

command line.

The following command will install the latest version of a module and its dependencies from the Python Package Index:

```
python -m pip install SomePackage
```

Note

For POSIX users (including macOS and Linux users), the examples in this guide assume the use of a virtual environment.

For Windows users, the examples in this guide assume that the option to adjust the system PATH environment variable was selected when installing Python.

It's also possible to specify an exact or minimum version directly on the command line. When using comparator operators such as `>`, `<` or some other special character which get interpreted by shell, the package name and the version should be enclosed within double quotes:

```
python -m pip install SomePackage==1.0.4    # specific v
python -m pip install "SomePackage>=1.0.4"  # minimum ve
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```
python -m pip install --upgrade SomePackage
```

More information and resources regarding `pip` and its capabilities can be found in the Python Packaging User Guide [https://packaging.python.org].

Creation of virtual environments is done through the **`venv`** module. Installing packages into an active virtual environment uses the commands shown above.

See also

Python Packaging User Guide: Installing Python Distribution Packages [https://packaging.python.org/installing/]

How do I …?

These are quick answers or links for some common tasks.

… install `pip` in versions of Python prior to Python 3.4?

Python only started bundling `pip` with Python 3.4. For earlier versions, `pip` needs to be "bootstrapped" as described in the Python Packaging User Guide.

See also

Python Packaging User Guide: Requirements for Installing Packages [https://packaging.python.org/installing/#requirements-for-installing-packages]

… install packages just for the current user?

Passing the `--user` option to `python -m pip install` will install a package just for the current user, rather than for all users of the system.

… install scientific Python packages?

A number of scientific Python packages have complex binary dependencies, and aren't currently easy to install using `pip` directly. At this point in time, it will often be easier for users to install these packages by other means [https://packaging.python.org/science/] rather than attempting to install them with `pip`.

See also

Python Packaging User Guide: Installing Scientific Packages [https://packaging.python.org/science/]

… work with multiple versions of Python installed in parallel?

On Linux, macOS, and other POSIX systems, use the versioned Python commands in combination with the `-m` switch to run the appropriate copy of `pip`:

```
python2   -m pip install SomePackage  # default Python 2
python2.7 -m pip install SomePackage  # specifically Pyt
python3   -m pip install SomePackage  # default Python 3
python3.4 -m pip install SomePackage  # specifically Pyt
```

Appropriately versioned `pip` commands may also be available.

On Windows, use the `py` Python launcher in combination with the `-m` switch:

```
py -2   -m pip install SomePackage  # default Python 2
py -2.7 -m pip install SomePackage  # specifically Pytho
py -3   -m pip install SomePackage  # default Python 3
py -3.4 -m pip install SomePackage  # specifically Pytho
```

Common installation issues

Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

Pip not installed

It is possible that `pip` does not get installed by default. One potential fix is:

```
python -m ensurepip --default-pip
```

There are also additional resources for installing pip. [https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date]

Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and macOS through the Python Package Index, this problem is expected to diminish over time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing scientific software [https://packaging.python.org/science/] that are not yet available as pre-built `wheel` files may also help with obtaining other binary extensions without needing to build them locally.

Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project's HOWTO collection, this collection is an effort to foster documentation that's more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Porting Python 2 Code to Python 3
- Porting Extension Modules to Python 3
- Curses Programming with Python
- Descriptor HowTo Guide
- Enum HOWTO
- Functional Programming HOWTO
- Logging HOWTO
- Logging Cookbook
- Regular Expression HOWTO
- Socket Programming HOWTO
- Sorting HOW TO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using The urllib Package
- Argparse Tutorial
- An introduction to the ipaddress module
- Argument Clinic How-To
- Instrumenting CPython with DTrace and SystemTap
- Annotations Best Practices
- Isolating Extension Modules

Porting Python 2 Code to Python 3

author

Brett Cannon

Abstract

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you figure out how best to support both Python 2 & 3 simultaneously.

If you are looking to port an extension module instead of pure Python code, please see Porting Extension Modules to Python 3.

If you would like to read one core Python developer's take on why Python 3 came into existence, you can read Nick Coghlan's Python 3 Q & A [https://ncoghlan-devs-python-notes.readthedocs.io/en/latest/python3/questions_and_answers.html] or Brett Cannon's Why Python 3 exists [https://snarky.ca/why-python-3-exists].

For help with porting, you can view the archived python-porting [https://mail.python.org/pipermail/python-porting/] mailing list.

The Short Explanation

To make your project be single-source Python 2/3 compatible, the basic steps are:

1. Only worry about supporting Python 2.7
2. Make sure you have good test coverage (coverage.py [https://pypi.org/project/coverage] can help; `python -m pip install coverage`)

3. Learn the differences between Python 2 & 3
4. Use Futurize [https://python-future.org/automatic_conversion.html] (or Modernize [https://python-modernize.readthedocs.io/]) to update your code (e.g. `python -m pip install future`)
5. Use Pylint [https://pypi.org/project/pylint] to help make sure you don't regress on your Python 3 support (`python -m pip install pylint`)
6. Use caniusepython3 [https://pypi.org/project/caniusepython3] to find out which of your dependencies are blocking your use of Python 3 (`python -m pip install caniusepython3`)
7. Once your dependencies are no longer blocking you, use continuous integration to make sure you stay compatible with Python 2 & 3 (tox [https://pypi.org/project/tox] can help test against multiple versions of Python; `python -m pip install tox`)
8. Consider using optional static type checking to make sure your type usage works in both Python 2 & 3 (e.g. use mypy [http://mypy-lang.org/] to check your typing under both Python 2 & Python 3; `python -m pip install mypy`).

Note

Note: Using `python -m pip install` guarantees that the `pip` you invoke is the one installed for the Python currently in use, whether it be a system-wide `pip` or one installed within a virtual environment.

Details

A key point about supporting Python 2 & 3 simultaneously is that you can start **today**! Even if your dependencies are not supporting Python 3 yet that does not mean you can't modernize your code **now** to support Python 3. Most changes required to support Python 3 lead to cleaner code using newer practices even in Python 2 code.

Another key point is that modernizing your Python 2 code to also support Python 3 is largely automated for you. While you might have to make some API decisions thanks to Python 3 clarifying text data versus binary data, the lower-level work is now mostly done

for you and thus can at least benefit from the automated changes immediately.

Keep those key points in mind while you read on about the details of porting your code to support Python 2 & 3 simultaneously.

Drop support for Python 2.6 and older

While you can make Python 2.5 work with Python 3, it is **much** easier if you only have to work with Python 2.7. If dropping Python 2.5 is not an option then the six [https://pypi.org/project/six] project can help you support Python 2.5 & 3 simultaneously (`python -m pip install six`). Do realize, though, that nearly all the projects listed in this HOWTO will not be available to you.

If you are able to skip Python 2.5 and older, then the required changes to your code should continue to look and feel like idiomatic Python code. At worst you will have to use a function instead of a method in some instances or have to import a function instead of using a built-in one, but otherwise the overall transformation should not feel foreign to you.

But you should aim for only supporting Python 2.7. Python 2.6 is no longer freely supported and thus is not receiving bugfixes. This means **you** will have to work around any issues you come across with Python 2.6. There are also some tools mentioned in this HOWTO which do not support Python 2.6 (e.g., Pylint [https://pypi.org/project/pylint]), and this will become more commonplace as time goes on. It will simply be easier for you if you only support the versions of Python that you have to support.

Make sure you specify the proper version support in your `setup.py` file

In your `setup.py` file you should have the proper trove classifier [https://pypi.org/classifiers] specifying what versions of Python you support. As your project does not support Python 3 yet you should at least have `Programming Language :: Python :: 2 :: Only` specified. Ideally you should also specify each major/minor version of Python that you do support, e.g. `Programming`

`Language :: Python :: 2.7`.

Have good test coverage

Once you have your code supporting the oldest version of Python 2 you want it to, you will want to make sure your test suite has good coverage. A good rule of thumb is that if you want to be confident enough in your test suite that any failures that appear after having tools rewrite your code are actual bugs in the tools and not in your code. If you want a number to aim for, try to get over 80% coverage (and don't feel bad if you find it hard to get better than 90% coverage). If you don't already have a tool to measure test coverage then coverage.py [https://pypi.org/project/coverage] is recommended.

Learn the differences between Python 2 & 3

Once you have your code well-tested you are ready to begin porting your code to Python 3! But to fully understand how your code is going to change and what you want to look out for while you code, you will want to learn what changes Python 3 makes in terms of Python 2. Typically the two best ways of doing that is reading the "What's New" doc for each release of Python 3 and the Porting to Python 3 [http://python3porting.com/] book (which is free online). There is also a handy cheat sheet [https://python-future.org/compatible_idioms.html] from the Python-Future project.

Update your code

Once you feel like you know what is different in Python 3 compared to Python 2, it's time to update your code! You have a choice between two tools in porting your code automatically: Futurize [https://python-future.org/automatic_conversion.html] and Modernize [https://python-modernize.readthedocs.io/]. Which tool you choose will depend on how much like Python 3 you want your code to be. Futurize [https://python-future.org/automatic_conversion.html] does its best to make Python 3 idioms and practices exist in Python 2, e.g. backporting the `bytes` type from Python 3 so that you have semantic parity between the major versions of Python. Modernize [https://python-modernize.readthedocs.io/], on the other hand, is more conservative and targets a Python 2/3 subset of Python, directly relying on six

[https://pypi.org/project/six] to help provide compatibility. As Python 3 is the future, it might be best to consider Futurize to begin adjusting to any new practices that Python 3 introduces which you are not accustomed to yet.

Regardless of which tool you choose, they will update your code to run under Python 3 while staying compatible with the version of Python 2 you started with. Depending on how conservative you want to be, you may want to run the tool over your test suite first and visually inspect the diff to make sure the transformation is accurate. After you have transformed your test suite and verified that all the tests still pass as expected, then you can transform your application code knowing that any tests which fail is a translation failure.

Unfortunately the tools can't automate everything to make your code work under Python 3 and so there are a handful of things you will need to update manually to get full Python 3 support (which of these steps are necessary vary between the tools). Read the documentation for the tool you choose to use to see what it fixes by default and what it can do optionally to know what will (not) be fixed for you and what you may have to fix on your own (e.g. using `io.open()` over the built-in `open()` function is off by default in Modernize). Luckily, though, there are only a couple of things to watch out for which can be considered large issues that may be hard to debug if not watched for.

Division

In Python 3, `5 / 2 == 2.5` and not `2`; all division between `int` values result in a `float`. This change has actually been planned since Python 2.2 which was released in 2002. Since then users have been encouraged to add `from __future__ import division` to any and all files which use the `/` and `//` operators or to be running the interpreter with the `-Q` flag. If you have not been doing this then you will need to go through your code and do two things:

1. Add `from __future__ import division` to your files
2. Update any division operator as necessary to either use `//` to

use floor division or continue using `/` and expect a float

The reason that `/` isn't simply translated to `//` automatically is that if an object defines a `__truediv__` method but not `__floordiv__` then your code would begin to fail (e.g. a user-defined class that uses `/` to signify some operation but not `//` for the same thing or at all).

Text versus binary data

In Python 2 you could use the `str` type for both text and binary data. Unfortunately this confluence of two different concepts could lead to brittle code which sometimes worked for either kind of data, sometimes not. It also could lead to confusing APIs if people didn't explicitly state that something that accepted `str` accepted either text or binary data instead of one specific type. This complicated the situation especially for anyone supporting multiple languages as APIs wouldn't bother explicitly supporting `unicode` when they claimed text data support.

To make the distinction between text and binary data clearer and more pronounced, Python 3 did what most languages created in the age of the internet have done and made text and binary data distinct types that cannot blindly be mixed together (Python predates widespread access to the internet). For any code that deals only with text or only binary data, this separation doesn't pose an issue. But for code that has to deal with both, it does mean you might have to now care about when you are using text compared to binary data, which is why this cannot be entirely automated.

To start, you will need to decide which APIs take text and which take binary (it is **highly** recommended you don't design APIs that can take both due to the difficulty of keeping the code working; as stated earlier it is difficult to do well). In Python 2 this means making sure the APIs that take text can work with `unicode` and those that work with binary data work with the `bytes` type from Python 3 (which is a subset of `str` in Python 2 and acts as an alias for `bytes` type in Python 2). Usually the biggest issue is realizing which methods exist on which types in Python 2 & 3 simultaneously (for text that's `unicode` in Python 2 and `str` in Python 3, for

binary that's `str/bytes` in Python 2 and `bytes` in Python 3). The following table lists the **unique** methods of each data type across Python 2 & 3 (e.g., the `decode()` method is usable on the equivalent binary data type in either Python 2 or 3, but it can't be used by the textual data type consistently between Python 2 and 3 because `str` in Python 3 doesn't have the method). Do note that as of Python 3.5 the `__mod__` method was added to the bytes type.

Binary data	Textual data
decode	
encode	
format	
isdecimal	
isnumeric	

Making the distinction easier to handle can be accomplished by encoding and decoding between binary data and text at the edge of your code. This means that when you receive text in binary data, you should immediately decode it. And if your code needs to send text as binary data then encode it as late as possible. This allows your code to work with only text internally and thus eliminates having to keep track of what type of data you are working with.

The next issue is making sure you know whether the string literals in your code represent text or binary data. You should add a `b` prefix to any literal that presents binary data. For text you should add a `u` prefix to the text literal. (there is a **`__future__`** import to force all unspecified literals to be Unicode, but usage has shown it isn't as effective as adding a `b` or `u` prefix to all literals explicitly)

As part of this dichotomy you also need to be careful about opening files. Unless you have been working on Windows, there is a chance you have not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the **`io`** module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing binary data to be read and/or written) or textual access (allowing text data to be read and/or written). You should also use **`io.open()`** for opening files instead of the built-in **`open()`** function as the **`io`**

module is consistent from Python 2 to 3 while the built-in **`open()`** function is not (in Python 3 it's actually **`io.open()`**). Do not bother with the outdated practice of using **`codecs.open()`** as that's only necessary for keeping compatibility with Python 2.5.

The constructors of both `str` and `bytes` have different semantics for the same arguments between Python 2 & 3. Passing an integer to `bytes` in Python 2 will give you the string representation of the integer: `bytes(3) == '3'`. But in Python 3, an integer argument to `bytes` will give you a bytes object as long as the integer specified, filled with null bytes: `bytes(3) == b'\x00\x00\x00'`. A similar worry is necessary when passing a bytes object to `str`. In Python 2 you just get the bytes object back: `str(b'3') == b'3'`. But in Python 3 you get the string representation of the bytes object: `str(b'3') == "b'3'"`.

Finally, the indexing of binary data requires careful handling (slicing does **not** require any special handling). In Python 2, `b'123'[1] == b'2'` while in Python 3 `b'123'[1] == 50`. Because binary data is simply a collection of binary numbers, Python 3 returns the integer value for the byte you index on. But in Python 2 because `bytes == str`, indexing returns a one-item slice of bytes. The six [https://pypi.org/project/six] project has a function named `six.indexbytes()` which will return an integer like in Python 3: `six.indexbytes(b'123', 1)`.

To summarize:

1. Decide which of your APIs take text and which take binary data
2. Make sure that your code that works with text also works with `unicode` and code for binary data works with `bytes` in Python 2 (see the table above for what methods you cannot use for each type)
3. Mark all binary literals with a `b` prefix, textual literals with a `u` prefix
4. Decode binary data to text as soon as possible, encode text as binary data as late as possible
5. Open files using **`io.open()`** and make sure to specify the `b` mode when appropriate
6. Be careful when indexing into binary data

Use feature detection instead of version detection

Inevitably you will have code that has to choose what to do based on what version of Python is running. The best way to do this is with feature detection of whether the version of Python you're running under supports what you need. If for some reason that doesn't work then you should make the version check be against Python 2 and not Python 3. To help explain this, let's look at an example.

Let's pretend that you need access to a feature of `importlib` that is available in Python's standard library since Python 3.3 and available for Python 2 through importlib2 [https://pypi.org/project/importlib2] on PyPI. You might be tempted to write code to access e.g. the `importlib.abc` module by doing the following:

```
import sys

if sys.version_info[0] == 3:
    from importlib import abc
else:
    from importlib2 import abc
```

The problem with this code is what happens when Python 4 comes out? It would be better to treat Python 2 as the exceptional case instead of Python 3 and assume that future Python versions will be more compatible with Python 3 than Python 2:

```
import sys

if sys.version_info[0] > 2:
    from importlib import abc
else:
    from importlib2 import abc
```

The best solution, though, is to do no version detection at all and instead rely on feature detection. That avoids any potential issues of getting the version detection wrong and helps keep you future-compatible:

```
try:
    from importlib import abc
except ImportError:
    from importlib2 import abc
```

Prevent compatibility regressions

Once you have fully translated your code to be compatible with Python 3, you will want to make sure your code doesn't regress and stop working under Python 3. This is especially true if you have a dependency which is blocking you from actually running under Python 3 at the moment.

To help with staying compatible, any new modules you create should have at least the following block of code at the top of it:

```
from __future__ import absolute_import
from __future__ import division
from __future__ import print_function
```

You can also run Python 2 with the `-3` flag to be warned about various compatibility issues your code triggers during execution. If you turn warnings into errors with `-Werror` then you can make sure that you don't accidentally miss a warning.

You can also use the Pylint [https://pypi.org/project/pylint] project and its `--py3k` flag to lint your code to receive warnings when your code begins to deviate from Python 3 compatibility. This also prevents you from having to run Modernize [https://python-modernize.readthedocs.io/] or Futurize [https://python-future.org/automatic_conversion.html] over your code regularly to catch compatibility regressions. This does require you only support Python 2.7 and Python 3.4 or newer as that is Pylint's minimum Python version support.

Check which dependencies block your transition

After you have made your code compatible with Python 3 you should begin to care about whether your dependencies have also been ported. The caniusepython3 [https://pypi.org/project/caniusepython3]

project was created to help you determine which projects – directly or indirectly – are blocking you from supporting Python 3. There is both a command-line tool as well as a web interface at https://caniusepython3.com.

The project also provides code which you can integrate into your test suite so that you will have a failing test when you no longer have dependencies blocking you from using Python 3. This allows you to avoid having to manually check your dependencies and to be notified quickly when you can start running on Python 3.

Update your `setup.py` file to denote Python 3 compatibility

Once your code works under Python 3, you should update the classifiers in your `setup.py` to contain `Programming Language :: Python :: 3` and to not specify sole Python 2 support. This will tell anyone using your code that you support Python 2 **and** 3. Ideally you will also want to add classifiers for each major/minor version of Python you now support.

Use continuous integration to stay compatible

Once you are able to fully run under Python 3 you will want to make sure your code always works under both Python 2 & 3. Probably the best tool for running your tests under multiple Python interpreters is tox [https://pypi.org/project/tox]. You can then integrate tox with your continuous integration system so that you never accidentally break Python 2 or 3 support.

You may also want to use the `-bb` flag with the Python 3 interpreter to trigger an exception when you are comparing bytes to strings or bytes to an int (the latter is available starting in Python 3.5). By default type-differing comparisons simply return `False`, but if you made a mistake in your separation of text/binary data handling or indexing on bytes you wouldn't easily find the mistake. This flag will raise an exception when these kinds of comparisons occur, making the mistake much easier to track down.

And that's mostly it! At this point your code base is compatible with

both Python 2 and 3 simultaneously. Your testing will also be set up so that you don't accidentally break Python 2 or 3 compatibility regardless of which version you typically run your tests under while developing.

Consider using optional static type checking

Another way to help port your code is to use a static type checker like mypy [http://mypy-lang.org/] or pytype [https://github.com/google/pytype] on your code. These tools can be used to analyze your code as if it's being run under Python 2, then you can run the tool a second time as if your code is running under Python 3. By running a static type checker twice like this you can discover if you're e.g. misusing binary data type in one version of Python compared to another. If you add optional type hints to your code you can also explicitly state whether your APIs use textual or binary data, helping to make sure everything functions as expected in both versions of Python.

Porting Extension Modules to Python 3

We recommend the following resources for porting extension modules to Python 3:

- The Migrating C extensions [http://python3porting.com/cextensions.html] chapter from *Supporting Python 3: An in-depth guide*, a book on moving from Python 2 to Python 3 in general, guides the reader through porting an extension module.
- The Porting guide [https://py3c.readthedocs.io/en/latest/guide.html] from the *py3c* project provides opinionated suggestions with supporting code.
- The Cython [https://cython.org/] and CFFI [https://cffi.readthedocs.io/en/latest/] libraries offer abstractions over Python's C API. Extensions generally need to be re-written to use one of them, but the library then handles differences between various Python versions and implementations.

Curses Programming with Python

Author

A.M. Kuchling, Eric S. Raymond

Release

2.04

Abstract

This document describes how to use the `curses` extension module to control text-mode displays.

What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple

non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn't provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as Urwid [https://pypi.org/project/urwid/].

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn't include the **curses** module. A ported version called UniCurses [https://pypi.org/project/UniCurses] is available.

The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as **addstr()**, **mvaddstr()**, and **mvwaddstr()** into a single **addstr()** method. You'll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.

Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the **`initscr()`** function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, **`initscr()`** returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the **`noecho()`** function.

```
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as **`curses.KEY_LEFT`**. To get curses to do the job, you'll have to enable keypad mode.

```
stdscr.keypad(True)
```

Terminating a curses application is much easier than starting one. You'll need to call:

```
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the

endwin() function to restore the terminal to its original operating mode.

```
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the **curses.wrapper()** function and using it like this:

```
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
        stdscr.addstr(i, 0, '10 divided by {} is {}'.for

    stdscr.refresh()
    stdscr.getkey()

wrapper(main)
```

The **wrapper()** function takes a callable object and does the initializations described above, also initializing colors if color support is present. **wrapper()** then runs your provided callable. Once the callable returns, **wrapper()** will restore the original state of the terminal. The callable is called inside a **try**…**except** that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won't be left in a funny state on exception and you'll be able to read the exception's

message and traceback.

Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the **`initscr()`** function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The **`newwin()`** function creates a new window of a given size, returning the new window object.

```
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order *y,x*, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the *x* coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the **`curses.LINES`** and **`curses.COLS`** variables to obtain the *y* and *x* sizes. Legal coordinates will then extend from `(0,0)` to `(curses.LINES - 1, curses.COLS - 1)`.

When you call a method to display or erase text, the effect doesn't immediately show up on the display. Instead you must call the **`refresh()`** method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the

most efficient manner when you call **`refresh()`**. For example, if your program displays some text in a window and then clears the window, there's no need to send the original text because they're never visible.

In practice, explicitly telling curses to redraw a window doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling `stdscr.refresh()` or the **`refresh()`** method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; addch() is
# explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y,x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the scr
# (0,0) : coordinate of upper-left corner of pad area to
# (5,5) : coordinate of upper-left corner of window area
#         with pad content.
# (20, 75) : coordinate of lower-right corner of window
#          : filled with pad content.
pad.refresh( 0,0, 5,5, 20,75)
```

The **`refresh()`** call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. **`refresh()`** actually does two things:

1. Calls the **`noutrefresh()`** method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function **`doupdate()`** function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call **`noutrefresh()`** on a number of windows to update the data structure, and then call **`doupdate()`** to update the screen.

Displaying Text

From a C programmer's point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, **`addstr()`** displays a string at the current cursor location in the `stdscr` window, while **`mvaddstr()`** moves to a given y,x coordinate first before displaying the string. **`waddstr()`** is just like **`addstr()`**, but allows specifying a window to use instead of using `stdscr` by default. **`mvwaddstr()`** allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as **`addstr()`** accept multiple argument forms. Usually there are four different forms.

Form	Description
str or *ch*	Display the string *str* or character *ch* at the current position
str or *ch*, *attr*	Display the string *str* or character *ch*, using attribute *attr* at the current position
y,x	Move to position *y,x* within the window, and display *str* or *ch*
y,x, *str* or *ch*, *attr*	Move to position *y,x* within the window, and display *str* or *ch*, using attribute *attr*

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They'll be explained in more detail in the next subsection.

The **addstr()** method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's **encoding** attribute; this defaults to the default system encoding as returned by **locale.getencoding()**.

The **addch()** methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, **ACS_PLMINUS** is a +/- symbol, and **ACS_ULCORNER** is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the *y,x* coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won't be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn't need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there's a `leaveok(bool)` function that's a synonym for **curs_set()**. When *bool* is true, the curses library will attempt to suppress the flashing cursor, and you won't need to worry about leaving it in odd locations.

Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn't guarantee that all the possible combinations are available, or that they're all visually distinct. That depends on the ability of the terminal being used, so it's safest to stick to the most commonly available attributes, listed here.

Attribute	Description
A_BLINK	Blinking text
A_BOLD	Extra bright or bold text
A_DIM	Half bright text
A_REVERSE	Reverse-video text
A_STANDOUT	The best highlighting mode available
A_UNDERLINE	Underlined text

So, to display a reverse-video status line on the top line of the screen, you could code:

```
stdscr.addstr(0, 0, "Current mode: Typing mode",
              curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the **start_color()** function soon after calling **initscr()**, to initialize the default color set (the **curses.wrapper()** function does this automatically). Once that's done, the **has_colors()** function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling 'color', instead of the Canadian/British spelling 'colour'. If you're used to the British spelling, you'll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the **color_pair()** function; this can be bitwise-OR'ed with other attributes such as **A_REVERSE**, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair *n*, to foreground color f and background color b. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and **`start_color()`** initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The **`curses`** module defines named constants for each of these colors: **`curses.COLOR_BLACK`**, **`curses.COLOR_RED`**, and so forth.

Let's put all this together. To change color 1 to red text on a white background, you would call:

```
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn't support this, so I'm unable to try it out, and can't provide any examples. You can check if your terminal can do this by calling **`can_change_color()`**, which returns `True` if the capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.

User Input

The C curses library offers only very simple input mechanisms.

Python's **curses** module adds a basic text-input widget. (Other libraries such as Urwid [https://pypi.org/project/urwid/] have more extensive collections of widgets.)

There are two methods for getting input from a window:

- **getch()** refreshes the screen and then waits for the user to hit a key, displaying the key if **echo()** has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- **getkey()** does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It's possible to not wait for the user using the **nodelay()** window method. After `nodelay(True)`, **getch()** and **getkey()** for the window become non-blocking. To signal that no input is ready, **getch()** returns `curses.ERR` (a value of -1) and **getkey()** raises an exception. There's also a **halfdelay()** function, which can be used to (in effect) set a timer on each **getch()**; if no input becomes available within a specified delay (measured in tenths of a second), curses raises an exception.

The **getch()** method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as **curses.KEY_PPAGE**, **curses.KEY_HOME**, or **curses.KEY_LEFT**. The main loop of your program may look something like this:

```
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break  # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0
```

The **curses.ascii** module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, **curses.ascii.ctrl()** returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, **getstr()**. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```
curses.echo()             # Enable echoing of characters

# Get a 15-character string, with the cursor on the top
s = stdscr.getstr(0,0, 15)
```

The **curses.textpad** module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the **Textbox** class support editing with input validation and gathering the edit results either with or without trailing spaces. Here's an example:

```
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G t

    editwin = curses.newwin(5,30, 2,1)
    rectangle(stdscr, 1,0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
```

```
message = box.gather()
```

See the library documentation on **curses.textpad** for more details.

For More Information

This HOWTO doesn't cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the **curses** module is now reasonably complete. You should browse it next.

If you're in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it's ncurses or a proprietary Unix vendor's. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and **ACS_*** characters available to you.

Because the curses API is so large, some functions aren't supported in the Python interface. Often this isn't because they're difficult to implement, but because no one has needed them yet. Also, Python doesn't yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see the Python Developer's Guide [https://devguide.python.org/] to learn more about submitting patches to Python.

Descriptors let objects customize attribute lookup, storage, and deletion.

This guide has four major sections:

1. The “primer” gives a basic overview, moving gently from simple examples, adding one feature at a time. Start here if you’re new to descriptors.
2. The second section shows a complete, practical descriptor example. If you already know the basics, start there.
3. The third section provides a more technical tutorial that goes into the detailed mechanics of how descriptors work. Most people don’t need this level of detail.
4. The last section has pure Python equivalents for built-in descriptors that are written in C. Read this if you’re curious about how functions turn into bound methods or about the implementation of common tools like **`classmethod()`**, **`staticmethod()`**, **`property()`**, and _slots_.

Primer

In this primer, we start with the most basic possible example and then we’ll add new capabilities one by one.

Simple example: A descriptor that returns a constant

The **`Ten`** class is a descriptor whose **`__get__()`** method always returns the constant `10`:

```
class Ten:
    def __get__(self, obj, objtype=None):
        return 10
```

To use the descriptor, it must be stored as a class variable in another class:

```
class A:
    x = 5                                 # Regular class attribut
    y = Ten()                             # Descriptor instance
```

An interactive session shows the difference between normal attribute lookup and descriptor lookup:

```
>>> a = A()                               # Make an instance of cl
>>> a.x                                   # Normal attribute looku
5
>>> a.y                                   # Descriptor lookup
10
```

In the `a.x` attribute lookup, the dot operator finds `'x': 5` in the class dictionary. In the `a.y` lookup, the dot operator finds a descriptor instance, recognized by its `__get__` method. Calling that method returns `10`.

Note that the value `10` is not stored in either the class dictionary or the instance dictionary. Instead, the value `10` is computed on demand.

This example shows how a simple descriptor works, but it isn't very useful. For retrieving constants, normal attribute lookup would be better.

In the next section, we'll create something more useful, a dynamic lookup.

Dynamic lookups

Interesting descriptors typically run computations instead of returning constants:

```
import os

class DirectorySize:

    def __get__(self, obj, objtype=None):
        return len(os.listdir(obj.dirname))
```

```
class Directory:

    size = DirectorySize()              # Descriptor ins

    def __init__(self, dirname):
        self.dirname = dirname          # Regular instar
```

An interactive session shows that the lookup is dynamic — it computes different, updated answers each time:

```
>>> s = Directory('songs')
>>> g = Directory('games')
>>> s.size                              # The songs dire
20
>>> g.size                              # The games dire
3
>>> os.remove('games/chess')            # Delete a game
>>> g.size                              # File count is
2
```

Besides showing how descriptors can run computations, this example also reveals the purpose of the parameters to **`__get__()`**. The *self* parameter is *size*, an instance of *DirectorySize*. The *obj* parameter is either *g* or *s*, an instance of *Directory*. It is the *obj* parameter that lets the **`__get__()`** method learn the target directory. The *objtype* parameter is the class *Directory*.

Managed attributes

A popular use for descriptors is managing access to instance data. The descriptor is assigned to a public attribute in the class dictionary while the actual data is stored as a private attribute in the instance dictionary. The descriptor's **`__get__()`** and **`__set__()`** methods are triggered when the public attribute is accessed.

In the following example, *age* is the public attribute and *_age* is the private attribute. When the public attribute is accessed, the descriptor logs the lookup or update:

```
import logging

logging.basicConfig(level=logging.INFO)

class LoggedAgeAccess:

    def __get__(self, obj, objtype=None):
        value = obj._age
        logging.info('Accessing %r giving %r', 'age', va
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', 'age', value)
        obj._age = value

class Person:

    age = LoggedAgeAccess()             # Descriptor ins

    def __init__(self, name, age):
        self.name = name                # Regular instan
        self.age = age                  # Calls __set__(

    def birthday(self):
        self.age += 1                   # Calls both __g
```

An interactive session shows that all access to the managed attribute *age* is logged, but that the regular attribute *name* is not logged:

```
>>> mary = Person('Mary M', 30)         # The initial ag
INFO:root:Updating 'age' to 30
>>> dave = Person('David D', 40)
INFO:root:Updating 'age' to 40

>>> vars(mary)                          # The actual dat
{'name': 'Mary M', '_age': 30}
>>> vars(dave)
{'name': 'David D', '_age': 40}
```

```
>>> mary.age                               # Access the dat
INFO:root:Accessing 'age' giving 30
30
>>> mary.birthday()                        # Updates are lo
INFO:root:Accessing 'age' giving 30
INFO:root:Updating 'age' to 31

>>> dave.name                              # Regular attrib
'David D'
>>> dave.age                               # Only the manag
INFO:root:Accessing 'age' giving 40
40
```

One major issue with this example is that the private name *_age* is hardwired in the *LoggedAgeAccess* class. That means that each instance can only have one logged attribute and that its name is unchangeable. In the next example, we'll fix that problem.

Customized names

When a class uses descriptors, it can inform each descriptor about which variable name was used.

In this example, the **`Person`** class has two descriptor instances, *name* and *age*. When the **`Person`** class is defined, it makes a callback to **`__set_name__()`** in *LoggedAccess* so that the field names can be recorded, giving each descriptor its own *public_name* and *private_name*:

```
import logging

logging.basicConfig(level=logging.INFO)

class LoggedAccess:

    def __set_name__(self, owner, name):
        self.public_name = name
        self.private_name = '_' + name
```

```
    def __get__(self, obj, objtype=None):
        value = getattr(obj, self.private_name)
        logging.info('Accessing %r giving %r', self.publ
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', self.public_na
        setattr(obj, self.private_name, value)

class Person:

    name = LoggedAccess()                # First descrip
    age = LoggedAccess()                 # Second descri

    def __init__(self, name, age):
        self.name = name                 # Calls the fir
        self.age = age                   # Calls the sec

    def birthday(self):
        self.age += 1
```

An interactive session shows that the **`Person`** class has called **`__set_name__()`** so that the field names would be recorded. Here we call **`vars()`** to look up the descriptor without triggering it:

```
>>> vars(vars(Person)['name'])
{'public_name': 'name', 'private_name': '_name'}
>>> vars(vars(Person)['age'])
{'public_name': 'age', 'private_name': '_age'}
```

The new class now logs access to both *name* and *age*:

```
>>> pete = Person('Peter P', 10)
INFO:root:Updating 'name' to 'Peter P'
INFO:root:Updating 'age' to 10
>>> kate = Person('Catherine C', 20)
INFO:root:Updating 'name' to 'Catherine C'
INFO:root:Updating 'age' to 20
```

The two *Person* instances contain only the private names:

```
>>> vars(pete)
{'_name': 'Peter P', '_age': 10}
>>> vars(kate)
{'_name': 'Catherine C', '_age': 20}
```

Closing thoughts

A descriptor is what we call any object that defines **`__get__()`**, **`__set__()`**, or **`__delete__()`**.

Optionally, descriptors can have a **`__set_name__()`** method. This is only used in cases where a descriptor needs to know either the class where it was created or the name of class variable it was assigned to. (This method, if present, is called even if the class is not a descriptor.)

Descriptors get invoked by the dot operator during attribute lookup. If a descriptor is accessed indirectly with `vars(some_class)[descriptor_name]`, the descriptor instance is returned without invoking it.

Descriptors only work when used as class variables. When put in instances, they have no effect.

The main motivation for descriptors is to provide a hook allowing objects stored in class variables to control what happens during attribute lookup.

Traditionally, the calling class controls what happens during lookup. Descriptors invert that relationship and allow the data being looked-up to have a say in the matter.

Descriptors are used throughout the language. It is how functions turn into bound methods. Common tools like **`classmethod()`**, **`staticmethod()`**, **`property()`**, and **`functools.cached_property()`** are all implemented as descriptors.

Complete Practical Example

In this example, we create a practical and powerful tool for locating notoriously hard to find data corruption bugs.

Validator class

A validator is a descriptor for managed attribute access. Prior to storing any data, it verifies that the new value meets various type and range restrictions. If those restrictions aren't met, it raises an exception to prevent data corruption at its source.

This **`Validator`** class is both an abstract base class and a managed attribute descriptor:

```
from abc import ABC, abstractmethod

class Validator(ABC):

    def __set_name__(self, owner, name):
        self.private_name = '_' + name

    def __get__(self, obj, objtype=None):
        return getattr(obj, self.private_name)

    def __set__(self, obj, value):
        self.validate(value)
        setattr(obj, self.private_name, value)

    @abstractmethod
    def validate(self, value):
        pass
```

Custom validators need to inherit from **`Validator`** and must supply a **`validate()`** method to test various restrictions as needed.

Custom validators

Here are three practical data validation utilities:

1. **`OneOf`** verifies that a value is one of a restricted set of options.
2. **`Number`** verifies that a value is either an **`int`** or **`float`**. Optionally, it verifies that a value is between a given minimum or maximum.
3. **`String`** verifies that a value is a **`str`**. Optionally, it validates a given minimum or maximum length. It can validate a user-defined predicate [https://en.wikipedia.org/wiki/Predicate_(mathematical_logic)] as well.

```
class OneOf(Validator):

    def __init__(self, *options):
        self.options = set(options)

    def validate(self, value):
        if value not in self.options:
            raise ValueError(f'Expected {value!r} to be

class Number(Validator):

    def __init__(self, minvalue=None, maxvalue=None):
        self.minvalue = minvalue
        self.maxvalue = maxvalue

    def validate(self, value):
        if not isinstance(value, (int, float)):
            raise TypeError(f'Expected {value!r} to be a
        if self.minvalue is not None and value < self.mi
            raise ValueError(
                f'Expected {value!r} to be at least {sel
            )
        if self.maxvalue is not None and value > self.ma
            raise ValueError(
                f'Expected {value!r} to be no more than
            )
```

```
class String(Validator):

    def __init__(self, minsize=None, maxsize=None, predi
        self.minsize = minsize
        self.maxsize = maxsize
        self.predicate = predicate

    def validate(self, value):
        if not isinstance(value, str):
            raise TypeError(f'Expected {value!r} to be a
        if self.minsize is not None and len(value) < sel
            raise ValueError(
                f'Expected {value!r} to be no smaller th
            )
        if self.maxsize is not None and len(value) > sel
            raise ValueError(
                f'Expected {value!r} to be no bigger tha
            )
        if self.predicate is not None and not self.predi
            raise ValueError(
                f'Expected {self.predicate} to be true f
            )
```

Practical application

Here's how the data validators can be used in a real class:

```
class Component:

    name = String(minsize=3, maxsize=10, predicate=str.i
    kind = OneOf('wood', 'metal', 'plastic')
    quantity = Number(minvalue=0)

    def __init__(self, name, kind, quantity):
        self.name = name
        self.kind = kind
        self.quantity = quantity
```

The descriptors prevent invalid instances from being created:

```
>>> Component('Widget', 'metal', 5)      # Blocked: 'Wid
Traceback (most recent call last):
    ...
ValueError: Expected <method 'isupper' of 'str' objects>

>>> Component('WIDGET', 'metle', 5)      # Blocked: 'met
Traceback (most recent call last):
    ...
ValueError: Expected 'metle' to be one of {'metal', 'pla

>>> Component('WIDGET', 'metal', -5)     # Blocked: -5 i
Traceback (most recent call last):
    ...
ValueError: Expected -5 to be at least 0
>>> Component('WIDGET', 'metal', 'V')    # Blocked: 'V'
Traceback (most recent call last):
    ...
TypeError: Expected 'V' to be an int or float

>>> c = Component('WIDGET', 'metal', 5)  # Allowed:  The
```

Technical Tutorial

What follows is a more technical tutorial for the mechanics and details of how descriptors work.

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Provides an example showing how object relational mappings work.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works.

Definition and introduction

In general, a descriptor is an attribute value that has one of the

methods in the descriptor protocol. Those methods are **`__get__()`**, **`__set__()`**, and **`__delete__()`**. If any of those methods are defined for an attribute, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the method resolution order of `type(a)`. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and **`super()`**. They are used throughout Python itself. Descriptors simplify the underlying C code and offer a flexible set of new tools for everyday Python programs.

Descriptor protocol

```
descr.__get__(self, obj, type=None) -> value

descr.__set__(self, obj, value) -> None

descr.__delete__(self, obj) -> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines **`__set__()`** or **`__delete__()`**, it is considered a data descriptor. Descriptors that only define **`__get__()`** are called non-data descriptors (they are often used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has

an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both **`__get__()`** and **`__set__()`** with the **`__set__()`** raising an **`AttributeError`** when called. Defining the **`__set__()`** method with an exception raising placeholder is enough to make it a data descriptor.

Overview of descriptor invocation

A descriptor can be called directly with `desc.__get__(obj)` or `desc.__get__(None, cls)`.

But it is more common for a descriptor to be invoked automatically from attribute access.

The expression `obj.x` looks up the attribute `x` in the chain of namespaces for `obj`. If the search finds a descriptor outside of the instance `__dict__`, its **`__get__()`** method is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object, class, or instance of super.

Invocation from an instance

Instance lookup scans through a chain of namespaces giving data descriptors the highest priority, followed by instance variables, then non-data descriptors, then class variables, and lastly **`__getattr__()`** if it is provided.

If a descriptor is found for `a.x`, then it is invoked with: `desc.__get__(a, type(a))`.

The logic for a dotted lookup is in **`object.__getattribute__()`**. Here is a pure Python equivalent:

```
def find_name_in_mro(cls, name, default):
    "Emulate _PyType_Lookup() in Objects/typeobject.c"
    for base in cls.__mro__:
```

```
        if name in vars(base):
            return vars(base)[name]
    return default

def object_getattribute(obj, name):
    "Emulate PyObject_GenericGetAttr() in Objects/object
    null = object()
    objtype = type(obj)
    cls_var = find_name_in_mro(objtype, name, null)
    descr_get = getattr(type(cls_var), '__get__', null)
    if descr_get is not null:
        if (hasattr(type(cls_var), '__set__')
            or hasattr(type(cls_var), '__delete__')):
            return descr_get(cls_var, obj, objtype)
    if hasattr(obj, '__dict__') and name in vars(obj):
        return vars(obj)[name]
    if descr_get is not null:
        return descr_get(cls_var, obj, objtype)
    if cls_var is not null:
        return cls_var
    raise AttributeError(name)
```

Note, there is no **`__getattr__()`** hook in the **`__getattribute__()`** code. That is why calling **`__getattribute__()`** directly or with `super().__getattribute__` will bypass **`__getattr__()`** entirely.

Instead, it is the dot operator and the **`getattr()`** function that are responsible for invoking **`__getattr__()`** whenever **`__getattribute__()`** raises an **`AttributeError`**. Their logic is encapsulated in a helper function:

```
def getattr_hook(obj, name):
    "Emulate slot_tp_getattr_hook() in Objects/typeobjec
    try:
        return obj.__getattribute__(name)
    except AttributeError:
        if not hasattr(type(obj), '__getattr__'):
```

```
            raise
    return type(obj).__getattr__(obj, name)
```

Invocation from a class

The logic for a dotted lookup such as `A.x` is in **`type.__getattribute__()`**. The steps are similar to those for **`object.__getattribute__()`** but the instance dictionary lookup is replaced by a search through the class's method resolution order.

If a descriptor is found, it is invoked with `desc.__get__(None, A)`.

The full C implementation can be found in **`type_getattro()`** and **`_PyType_Lookup()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.11/Objects/typeobject.c].

Invocation from super

The logic for super's dotted lookup is in the **`__getattribute__()`** method for object returned by **`super()`**.

A dotted lookup such as `super(A, obj).m` searches `obj.__class__.__mro__` for the base class `B` immediately following `A` and then returns `B.__dict__['m'].__get__(obj, A)`. If not a descriptor, `m` is returned unchanged.

The full C implementation can be found in **`super_getattro()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.11/Objects/typeobject.c]. A pure Python equivalent can be found in Guido's Tutorial [https://www.python.org/download/releases/2.2.3/descrintro/#cooperation].

Summary of invocation logic

The mechanism for descriptors is embedded in the **`__getattribute__()`** methods for **`object`**, **`type`**, and **`super()`**.

The important points to remember are:

- Descriptors are invoked by the **`__getattribute__()`** method.
- Classes inherit this machinery from **`object`**, **`type`**, or **`super()`**.
- Overriding **`__getattribute__()`** prevents automatic descriptor calls because all the descriptor logic is in that method.
- **`object.__getattribute__()`** and **`type.__getattribute__()`** make different calls to **`__get__()`**. The first includes the instance and may include the class. The second puts in `None` for the instance and always includes the class.
- Data descriptors always override instance dictionaries.
- Non-data descriptors may be overridden by instance dictionaries.

Automatic name notification

Sometimes it is desirable for a descriptor to know what class variable name it was assigned to. When a new class is created, the **`type`** metaclass scans the dictionary of the new class. If any of the entries are descriptors and if they define **`__set_name__()`**, that method is called with two arguments. The *owner* is the class where the descriptor is used, and the *name* is the class variable the descriptor was assigned to.

The implementation details are in **`type_new()`** and **`set_names()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.11/Objects/typeobject.c].

Since the update logic is in **`type.__new__()`**, notifications only take place at the time of class creation. If descriptors are added to the class afterwards, **`__set_name__()`** will need to be called manually.

ORM example

The following code is a simplified skeleton showing how data

descriptors could be used to implement an object relational mapping [https://en.wikipedia.org/wiki/Object%E2%80%93relational_mapping].

The essential idea is that the data is stored in an external database. The Python instances only hold keys to the database's tables. Descriptors take care of lookups or updates:

```
class Field:

    def __set_name__(self, owner, name):
        self.fetch = f'SELECT {name} FROM {owner.table}
        self.store = f'UPDATE {owner.table} SET {name}=?

    def __get__(self, obj, objtype=None):
        return conn.execute(self.fetch, [obj.key]).fetch

    def __set__(self, obj, value):
        conn.execute(self.store, [value, obj.key])
        conn.commit()
```

We can use the **`Field`** class to define models [https://en.wikipedia.org/wiki/Database_model] that describe the schema for each table in a database:

```
class Movie:
    table = 'Movies'                    # Table name
    key = 'title'                       # Primary key
    director = Field()
    year = Field()

    def __init__(self, key):
        self.key = key

class Song:
    table = 'Music'
    key = 'title'
    artist = Field()
    year = Field()
    genre = Field()
```

```
    def __init__(self, key):
        self.key = key
```

To use the models, first connect to the database:

```
>>> import sqlite3
>>> conn = sqlite3.connect('entertainment.db')
```

An interactive session shows how data is retrieved from the database and how it can be updated:

```
>>> Movie('Star Wars').director
'George Lucas'
>>> jaws = Movie('Jaws')
>>> f'Released in {jaws.year} by {jaws.director}'
'Released in 1975 by Steven Spielberg'

>>> Song('Country Roads').artist
'John Denver'

>>> Movie('Star Wars').director = 'J.J. Abrams'
>>> Movie('Star Wars').director
'J.J. Abrams'
```

Pure Python Equivalents

The descriptor protocol is simple and offers exciting possibilities. Several use cases are so common that they have been prepackaged into built-in tools. Properties, bound methods, static methods, class methods, and _slots_ are all based on the descriptor protocol.

Properties

Calling `property()` is a succinct way of building a data descriptor that triggers a function call upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None) -> p
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C:
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property
```

To see how **`property()`** is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```
class Property:
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None,
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        if doc is None and fget is not None:
            doc = fget.__doc__
        self.__doc__ = doc
        self._name = ''

    def __set_name__(self, owner, name):
        self._name = name

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError(f"property '{self._name
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError(f"property '{self._name
        self.fset(obj, value)
```

```
    def __delete__(self, obj):
        if self.fdel is None:
            raise AttributeError(f"property '{self._name
        self.fdel(obj)

    def getter(self, fget):
        prop = type(self)(fget, self.fset, self.fdel, se
        prop._name = self._name
        return prop

    def setter(self, fset):
        prop = type(self)(self.fget, fset, self.fdel, se
        prop._name = self._name
        return prop

    def deleter(self, fdel):
        prop = type(self)(self.fget, self.fset, fdel, se
        prop._name = self._name
        return prop
```

The **`property()`** builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```
class Cell:
    ...

    @property
    def value(self):
        "Recalculate the cell before returning value"
        self.recalc()
        return self._value
```

Either the built-in **`property()`** or our **`Property()`** equivalent would work in this example.

Functions and methods

Python's object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Functions stored in class dictionaries get turned into methods when invoked. Methods only differ from regular functions in that the object instance is prepended to the other arguments. By convention, the instance is called *self* but could be called *this* or any other variable name.

Methods can be created manually with **`types.MethodType`** which is roughly equivalent to:

```
class MethodType:
    "Emulate PyMethod_Type in Objects/classobject.c"

    def __init__(self, func, obj):
        self.__func__ = func
        self.__self__ = obj

    def __call__(self, *args, **kwargs):
        func = self.__func__
        obj = self.__self__
        return func(obj, *args, **kwargs)
```

To support automatic creation of methods, functions include the **`__get__()`** method for binding methods during attribute access. This means that functions are non-data descriptors that return bound methods during dotted lookup from an instance. Here's how it works:

```
class Function:
    ...

    def __get__(self, obj, objtype=None):
```

```
        "Simulate func_descr_get() in Objects/funcobject
        if obj is None:
            return self
        return MethodType(self, obj)
```

Running the following class in the interpreter shows how the function descriptor works in practice:

```
class D:
    def f(self, x):
         return x
```

The function has a qualified name attribute to support introspection:

```
>>> D.f.__qualname__
'D.f'
```

Accessing the function through the class dictionary does not invoke **`__get__()`**. Instead, it just returns the underlying function object:

```
>>> D.__dict__['f']
<function D.f at 0x00C45070>
```

Dotted access from a class calls **`__get__()`** which just returns the underlying function unchanged:

```
>>> D.f
<function D.f at 0x00C45070>
```

The interesting behavior occurs during dotted access from an instance. The dotted lookup calls **`__get__()`** which returns a bound method object:

```
>>> d = D()
>>> d.f
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

Internally, the bound method stores the underlying function and the bound instance:

```
>>> d.f.__func__
<function D.f at 0x00C45070>

>>> d.f.__self__
<__main__.D object at 0x1012e1f98>
```

If you have ever wondered where *self* comes from in regular methods or where *cls* comes from in class methods, this is it!

Kinds of methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a **`__get__()`** method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms an `obj.f(*args)` call into `f(obj, *args)`. Calling `cls.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

	Called from an object	Called from a class
function	f(obj, *args)	f(*args)
staticmethod	f(*args)	f(*args)
classmethod	f(type(obj), *args)	f(cls, *args)

Static methods

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful

functions which are conceptually related but do not depend on the data. For instance, `erf(x)` is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: `s.erf(1.5) --> .9332` or `Sample.erf(1.5) --> .9332`.

Since static methods return the underlying function with no changes, the example calls are unexciting:

```
class E:
    @staticmethod
    def f(x):
        return x * 10

>>> E.f(3)
30
>>> E().f(3)
30
```

Using the non-data descriptor protocol, a pure Python version of **`staticmethod()`** would look like this:

```
class StaticMethod:
    "Emulate PyStaticMethod_Type() in Objects/funcobject

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, objtype=None):
        return self.f

    def __call__(self, *args, **kwds):
        return self.f(*args, **kwds)
```

Class methods

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```
class F:
    @classmethod
    def f(cls, x):
        return cls.__name__, x

>>> F.f(3)
('F', 3)
>>> F().f(3)
('F', 3)
```

This behavior is useful whenever the method only needs to have a class reference and does not rely on data stored in a specific instance. One use for class methods is to create alternate class constructors. For example, the classmethod **`dict.fromkeys()`** creates a new dictionary from a list of keys. The pure Python equivalent is:

```
class Dict(dict):
    @classmethod
    def fromkeys(cls, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c
        d = cls()
        for key in iterable:
            d[key] = value
        return d
```

Now a new dictionary of unique keys can be constructed like this:

```
>>> d = Dict.fromkeys('abracadabra')
>>> type(d) is Dict
True
>>> d
{'a': None, 'b': None, 'r': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of **`classmethod()`** would look like this:

```
class ClassMethod:
    "Emulate PyClassMethod_Type() in Objects/funcobject.
```

```
    def __init__(self, f):
        self.f = f

    def __get__(self, obj, cls=None):
        if cls is None:
            cls = type(obj)
        if hasattr(type(self.f), '__get__'):
            # This code path was added in Python 3.9
            # and was deprecated in Python 3.11.
            return self.f.__get__(cls, cls)
        return MethodType(self.f, cls)
```

The code path for `hasattr(type(self.f), '__get__')` was added in Python 3.9 and makes it possible for **`classmethod()`** to support chained decorators. For example, a classmethod and property could be chained together. In Python 3.11, this functionality was deprecated.

```
class G:
    @classmethod
    @property
    def __doc__(cls):
        return f'A doc for {cls.__name__!r}'

>>> G.__doc__
"A doc for 'G'"
```

Member objects and _slots_

When a class defines `__slots__`, it replaces instance dictionaries with a fixed-length array of slot values. From a user point of view that has several effects:

1. Provides immediate detection of bugs due to misspelled attribute assignments. Only attribute names specified in `__slots__` are allowed:

```
class Vehicle:
    __slots__ = ('id_number', 'make', 'model')
```

```
>>> auto = Vehicle()
>>> auto.id_nubmer = 'VYE483814LQEX'
Traceback (most recent call last):
    ...
AttributeError: 'Vehicle' object has no attribute 'id_nu
```

2. Helps create immutable objects where descriptors manage access to private attributes stored in `__slots__`:

```
class Immutable:

    __slots__ = ('_dept', '_name')          # Replace th

    def __init__(self, dept, name):
        self._dept = dept                   # Store to p
        self._name = name                   # Store to p

    @property                               # Read-only
    def dept(self):
        return self._dept

    @property
    def name(self):                         # Read-only
        return self._name

>>> mark = Immutable('Botany', 'Mark Watney')
>>> mark.dept
'Botany'
>>> mark.dept = 'Space Pirate'
Traceback (most recent call last):
    ...
AttributeError: property 'dept' of 'Immutable' object ha
>>> mark.location = 'Mars'
Traceback (most recent call last):
    ...
AttributeError: 'Immutable' object has no attribute 'loc
```

3. Saves memory. On a 64-bit Linux build, an instance with two attributes takes 48 bytes with `__slots__` and 152 bytes without.

This flyweight design pattern [https://en.wikipedia.org/wiki/Flyweight_pattern] likely only matters when a large number of instances are going to be created.

4. Improves speed. Reading instance variables is 35% faster with `__slots__` (as measured with Python 3.10 on an Apple M1 processor).

5. Blocks tools like **`functools.cached_property()`** which require an instance dictionary to function correctly:

```
from functools import cached_property

class CP:
    __slots__ = ()                              # Eliminates

    @cached_property                            # Requires a
    def pi(self):
        return 4 * sum((-1.0)**n / (2.0*n + 1.0)
                       for n in reversed(range(100_000))

>>> CP().pi
Traceback (most recent call last):
  ...
TypeError: No '__dict__' attribute on 'CP' instance to c
```

It is not possible to create an exact drop-in pure Python version of `__slots__` because it requires direct access to C structures and control over object memory allocation. However, we can build a mostly faithful simulation where the actual C structure for slots is emulated by a private `_slotvalues` list. Reads and writes to that private structure are managed by member descriptors:

```
null = object()

class Member:

    def __init__(self, name, clsname, offset):
        'Emulate PyMemberDef in Include/structmember.h'
        # Also see descr_new() in Objects/descrobject.c
```

```
        self.name = name
        self.clsname = clsname
        self.offset = offset

    def __get__(self, obj, objtype=None):
        'Emulate member_get() in Objects/descrobject.c'
        # Also see PyMember_GetOne() in Python/structmem
        if obj is None:
            return self
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        return value

    def __set__(self, obj, value):
        'Emulate member_set() in Objects/descrobject.c'
        obj._slotvalues[self.offset] = value

    def __delete__(self, obj):
        'Emulate member_delete() in Objects/descrobject.
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        obj._slotvalues[self.offset] = null

    def __repr__(self):
        'Emulate member_repr() in Objects/descrobject.c'
        return f'<Member {self.name!r} of {self.clsname!
```

The **`type.__new__()`** method takes care of adding member objects to class variables:

```
class Type(type):
    'Simulate how the type metaclass adds member objects

    def __new__(mcls, clsname, bases, mapping, **kwargs)
        'Emulate type_new() in Objects/typeobject.c'
        # type_new() calls PyTypeReady() which calls add
        slot_names = mapping.get('slot_names', [])
```

```
        for offset, name in enumerate(slot_names):
            mapping[name] = Member(name, clsname, offset
        return type.__new__(mcls, clsname, bases, mappin
```

The **`object.__new__()`** method takes care of creating instances that have slots instead of an instance dictionary. Here is a rough simulation in pure Python:

```
class Object:
    'Simulate how object.__new__() allocates memory for

    def __new__(cls, *args, **kwargs):
        'Emulate object_new() in Objects/typeobject.c'
        inst = super().__new__(cls)
        if hasattr(cls, 'slot_names'):
            empty_slots = [null] * len(cls.slot_names)
            object.__setattr__(inst, '_slotvalues', empt
        return inst

    def __setattr__(self, name, value):
        'Emulate _PyObject_GenericSetAttrWithDict() Obje
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in cl
            raise AttributeError(
                f'{cls.__name__!r} object has no attribu
            )
        super().__setattr__(name, value)

    def __delattr__(self, name):
        'Emulate _PyObject_GenericSetAttrWithDict() Obje
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in cl
            raise AttributeError(
                f'{cls.__name__!r} object has no attribu
            )
        super().__delattr__(name)
```

To use the simulation in a real class, just inherit from **`Object`** and set the metaclass to **`Type`**:

```
class H(Object, metaclass=Type):
    'Instance variables stored in slots'

    slot_names = ['x', 'y']

    def __init__(self, x, y):
        self.x = x
        self.y = y
```

At this point, the metaclass has loaded member objects for *x* and *y*:

```
>>> from pprint import pp
>>> pp(dict(vars(H)))
{'__module__': '__main__',
 '__doc__': 'Instance variables stored in slots',
 'slot_names': ['x', 'y'],
 '__init__': <function H.__init__ at 0x7fb5d302f9d0>,
 'x': <Member 'x' of 'H'>,
 'y': <Member 'y' of 'H'>}
```

When instances are created, they have a `slot_values` list where the attributes are stored:

```
>>> h = H(10, 20)
>>> vars(h)
{'_slotvalues': [10, 20]}
>>> h.x = 55
>>> vars(h)
{'_slotvalues': [55, 20]}
```

Misspelled or unassigned attributes will raise an exception:

```
>>> h.xz
Traceback (most recent call last):
    ...
AttributeError: 'H' object has no attribute 'xz'
```

Enum HOWTO

An **Enum** is a set of symbolic names bound to unique values. They are similar to global variables, but they offer a more useful **repr()**, grouping, type-safety, and a few other features.

They are most useful when you have a variable that can take one of a limited selection of values. For example, the days of the week:

```
>>> from enum import Enum
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
```

Or perhaps the RGB primary colors:

```
>>> from enum import Enum
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

As you can see, creating an **Enum** is as simple as writing a class that inherits from **Enum** itself.

Note

Case of Enum Members

Because Enums are used to represent constants we recommend using UPPER_CASE names for members, and will be using that

style in our examples.

Depending on the nature of the enum a member's value may or may not be important, but either way that value can be used to get the corresponding member:

```
>>> Weekday(3)
<Weekday.WEDNESDAY: 3>
```

As you can see, the `repr()` of a member shows the enum name, the member name, and the value. The `str()` of a member shows only the enum name and member name:

```
>>> print(Weekday.THURSDAY)
Weekday.THURSDAY
```

The *type* of an enumeration member is the enum it belongs to:

```
>>> type(Weekday.MONDAY)
<enum 'Weekday'>
>>> isinstance(Weekday.FRIDAY, Weekday)
True
```

Enum members have an attribute that contains just their **`name`**:

```
>>> print(Weekday.TUESDAY.name)
TUESDAY
```

Likewise, they have an attribute for their **`value`**:

```
>>> Weekday.WEDNESDAY.value
3
```

Unlike many languages that treat enumerations solely as name/value pairs, Python Enums can have behavior added. For example, **`datetime.date`** has two methods for returning the weekday: **`weekday()`** and **`isoweekday()`**. The difference is that one of them counts from 0-6 and the other from 1-7. Rather than keep track of that ourselves we can add a method to the **`Weekday`** enum to extract the day from the **`date`** instance and return the matching enum member:

```
@classmethod
def from_date(cls, date):
    return cls(date.isoweekday())
```

The complete **`Weekday`** enum now looks like this:

```
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
...     #
...     @classmethod
...     def from_date(cls, date):
...         return cls(date.isoweekday())
```

Now we can find out what today is! Observe:

```
>>> from datetime import date
>>> Weekday.from_date(date.today())
<Weekday.TUESDAY: 2>
```

Of course, if you're reading this on some other day, you'll see that day instead.

This **`Weekday`** enum is great if our variable only needs one day, but what if we need several? Maybe we're writing a function to plot chores during a week, and don't want to use a **`list`** – we could use a different type of **`Enum`**:

```
>>> from enum import Flag
>>> class Weekday(Flag):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 4
...     THURSDAY = 8
...     FRIDAY = 16
```

```
...     SATURDAY = 32
...     SUNDAY = 64
```

We've changed two things: we're inherited from **`Flag`**, and the values are all powers of 2.

Just like the original **`Weekday`** enum above, we can have a single selection:

```
>>> first_week_day = Weekday.MONDAY
>>> first_week_day
<Weekday.MONDAY: 1>
```

But **`Flag`** also allows us to combine several members into a single variable:

```
>>> weekend = Weekday.SATURDAY | Weekday.SUNDAY
>>> weekend
<Weekday.SATURDAY|SUNDAY: 96>
```

You can even iterate over a **`Flag`** variable:

```
>>> for day in weekend:
...     print(day)
Weekday.SATURDAY
Weekday.SUNDAY
```

Okay, let's get some chores set up:

```
>>> chores_for_ethan = {
...     'feed the cat': Weekday.MONDAY | Weekday.WEDNESD
...     'do the dishes': Weekday.TUESDAY | Weekday.THURS
...     'answer SO questions': Weekday.SATURDAY,
...     }
```

And a function to display the chores for a given day:

```
>>> def show_chores(chores, day):
...     for chore, days in chores.items():
...         if day in days:
...             print(chore)
```

```
>>> show_chores(chores_for_ethan, Weekday.SATURDAY)
answer SO questions
```

In cases where the actual values of the members do not matter, you can save yourself some work and use **`auto()`** for the values:

```
>>> from enum import auto
>>> class Weekday(Flag):
...     MONDAY = auto()
...     TUESDAY = auto()
...     WEDNESDAY = auto()
...     THURSDAY = auto()
...     FRIDAY = auto()
...     SATURDAY = auto()
...     SUNDAY = auto()
...     WEEKEND = SATURDAY | SUNDAY
```

Programmatic access to enumeration members and their attributes

Sometimes it's useful to access members in enumerations programmatically (i.e. situations where `Color.RED` won't do because the exact color is not known at program-writing time). `Enum` allows such access:

```
>>> Color(1)
<Color.RED: 1>
>>> Color(3)
<Color.BLUE: 3>
```

If you want to access enum members by *name*, use item access:

```
>>> Color['RED']
<Color.RED: 1>
>>> Color['GREEN']
<Color.GREEN: 2>
```

If you have an enum member and need its **`name`** or **`value`**:

```
>>> member = Color.RED
>>> member.name
'RED'
>>> member.value
1
```

Duplicating enum members and values

Having two enum members with the same name is invalid:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     SQUARE = 3
...
Traceback (most recent call last):
...
TypeError: 'SQUARE' already defined as 2
```

However, an enum member can have other names associated with it. Given two entries `A` and `B` with the same value (and `A` defined first), `B` is an alias for the member `A`. By-value lookup of the value of `A` will return the member `A`. By-name lookup of `A` will return the member `A`. By-name lookup of `B` will also return the member `A`:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     DIAMOND = 1
...     CIRCLE = 3
...     ALIAS_FOR_SQUARE = 2
...
>>> Shape.SQUARE
<Shape.SQUARE: 2>
>>> Shape.ALIAS_FOR_SQUARE
<Shape.SQUARE: 2>
>>> Shape(2)
<Shape.SQUARE: 2>
```

Note

Attempting to create a member with the same name as an already defined attribute (another member, a method, etc.) or attempting to create an attribute with the same name as a member is not allowed.

Ensuring unique enumeration values

By default, enumerations allow multiple names as aliases for the same value. When this behavior isn't desired, you can use the **`unique()`** decorator:

```
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
...     FOUR = 3
...
Traceback (most recent call last):
...
ValueError: duplicate values found in <enum 'Mistake'>:
```

Using automatic values

If the exact value is unimportant you can use **`auto`**:

```
>>> from enum import Enum, auto
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> [member.value for member in Color]
[1, 2, 3]
```

The values are chosen by **`_generate_next_value_()`**, which can be overridden:

```
>>> class AutoName(Enum):
...     def _generate_next_value_(name, start, count, la
...         return name
...
>>> class Ordinal(AutoName):
...     NORTH = auto()
...     SOUTH = auto()
...     EAST = auto()
...     WEST = auto()
...
>>> [member.value for member in Ordinal]
['NORTH', 'SOUTH', 'EAST', 'WEST']
```

Note

The **`_generate_next_value_()`** method must be defined before any members.

Iteration

Iterating over the members of an enum does not provide the aliases:

```
>>> list(Shape)
[<Shape.SQUARE: 2>, <Shape.DIAMOND: 1>, <Shape.CIRCLE: 3
>>> list(Weekday)
[<Weekday.MONDAY: 1>, <Weekday.TUESDAY: 2>, <Weekday.WED
```

Note that the aliases `Shape.ALIAS_FOR_SQUARE` and `Weekday.WEEKEND` aren't shown.

The special attribute `__members__` is a read-only ordered mapping of names to members. It includes all names defined in the enumeration, including the aliases:

```
>>> for name, member in Shape.__members__.items():
...     name, member
...
('SQUARE', <Shape.SQUARE: 2>)
```

```
('DIAMOND', <Shape.DIAMOND: 1>)
('CIRCLE', <Shape.CIRCLE: 3>)
('ALIAS_FOR_SQUARE', <Shape.SQUARE: 2>)
```

The `__members__` attribute can be used for detailed programmatic access to the enumeration members. For example, finding all the aliases:

```
>>> [name for name, member in Shape.__members__.items()
['ALIAS_FOR_SQUARE']
```

Note

Aliases for flags include values with multiple flags set, such as `3`, and no flags set, i.e. `0`.

Comparisons

Enumeration members are compared by identity:

```
>>> Color.RED is Color.RED
True
>>> Color.RED is Color.BLUE
False
>>> Color.RED is not Color.BLUE
True
```

Ordered comparisons between enumeration values are *not* supported. Enum members are not integers (but see IntEnum below):

```
>>> Color.RED < Color.BLUE
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: '<' not supported between instances of 'Color
```

Equality comparisons are defined though:

```
>>> Color.BLUE == Color.RED
```

```
False
>>> Color.BLUE != Color.RED
True
>>> Color.BLUE == Color.BLUE
True
```

Comparisons against non-enumeration values will always compare not equal (again, **`IntEnum`** was explicitly designed to behave differently, see below):

```
>>> Color.BLUE == 2
False
```

Allowed members and attributes of enumerations

Most of the examples above use integers for enumeration values. Using integers is short and handy (and provided by default by the Functional API), but not strictly enforced. In the vast majority of use-cases, one doesn't care what the actual value of an enumeration is. But if the value *is* important, enumerations can have arbitrary values.

Enumerations are Python classes, and can have methods and special methods as usual. If we have this enumeration:

```
>>> class Mood(Enum):
...     FUNKY = 1
...     HAPPY = 3
...
...     def describe(self):
...         # self is the member here
...         return self.name, self.value
...
...     def __str__(self):
...         return 'my custom str! {0}'.format(self.valu
...
...     @classmethod
...     def favorite_mood(cls):
```

```
...         # cls here is the enumeration
...         return cls.HAPPY
...
```

Then:

```
>>> Mood.favorite_mood()
<Mood.HAPPY: 3>
>>> Mood.HAPPY.describe()
('HAPPY', 3)
>>> str(Mood.FUNKY)
'my custom str! 1'
```

The rules for what is allowed are as follows: names that start and end with a single underscore are reserved by enum and cannot be used; all other attributes defined within an enumeration will become members of this enumeration, with the exception of special methods (**`__str__()`**, **`__add__()`**, etc.), descriptors (methods are also descriptors), and variable names listed in **`_ignore_`**.

Note: if your enumeration defines **`__new__()`** and/or **`__init__()`** then any value(s) given to the enum member will be passed into those methods. See Planet for an example.

Restricted Enum subclassing

A new **`Enum`** class must have one base enum class, up to one concrete data type, and as many **`object`**-based mixin classes as needed. The order of these base classes is:

```
class EnumName([mix-in, ...,] [data-type,] base-enum):
    pass
```

Also, subclassing an enumeration is allowed only if the enumeration does not define any members. So this is forbidden:

```
>>> class MoreColor(Color):
...     PINK = 17
...
Traceback (most recent call last):
```

```
...
TypeError: <enum 'MoreColor'> cannot extend <enum 'Color
```

But this is allowed:

```
>>> class Foo(Enum):
...     def some_behavior(self):
...         pass
...
>>> class Bar(Foo):
...     HAPPY = 1
...     SAD = 2
...
```

Allowing subclassing of enums that define members would lead to a violation of some important invariants of types and instances. On the other hand, it makes sense to allow sharing some common behavior between a group of enumerations. (See OrderedEnum for an example.)

Pickling

Enumerations can be pickled and unpickled:

```
>>> from test.test_enum import Fruit
>>> from pickle import dumps, loads
>>> Fruit.TOMATO is loads(dumps(Fruit.TOMATO))
True
```

The usual restrictions for pickling apply: picklable enums must be defined in the top level of a module, since unpickling requires them to be importable from that module.

Note

With pickle protocol version 4 it is possible to easily pickle enums nested in other classes.

It is possible to modify how enum members are pickled/unpickled

by defining **`__reduce_ex__()`** in the enumeration class.

Functional API

The **`Enum`** class is callable, providing the following functional API:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG')
>>> Animal
<enum 'Animal'>
>>> Animal.ANT
<Animal.ANT: 1>
>>> list(Animal)
[<Animal.ANT: 1>, <Animal.BEE: 2>, <Animal.CAT: 3>, <Ani
```

The semantics of this API resemble **`namedtuple`**. The first argument of the call to **`Enum`** is the name of the enumeration.

The second argument is the *source* of enumeration member names. It can be a whitespace-separated string of names, a sequence of names, a sequence of 2-tuples with key/value pairs, or a mapping (e.g. dictionary) of names to values. The last two options enable assigning arbitrary values to enumerations; the others auto-assign increasing integers starting with 1 (use the `start` parameter to specify a different starting value). A new class derived from **`Enum`** is returned. In other words, the above assignment to **`Animal`** is equivalent to:

```
>>> class Animal(Enum):
...     ANT = 1
...     BEE = 2
...     CAT = 3
...     DOG = 4
...
```

The reason for defaulting to `1` as the starting number and not `0` is that `0` is `False` in a boolean sense, but by default enum members all evaluate to `True`.

Pickling enums created with the functional API can be tricky as frame stack implementation details are used to try and figure out

which module the enumeration is being created in (e.g. it will fail if you use a utility function in a separate module, and also may not work on IronPython or Jython). The solution is to specify the module name explicitly as follows:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', module=__
```

Warning

If `module` is not supplied, and Enum cannot determine what it is, the new Enum members will not be unpicklable; to keep errors closer to the source, pickling will be disabled.

The new pickle protocol 4 also, in some circumstances, relies on **`__qualname__`** being set to the location where pickle will be able to find the class. For example, if the class was made available in class SomeData in the global scope:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', qualname=
```

The complete signature is:

```
Enum(
    value='NewEnumName',
    names=<...>,
    *,
    module='...',
    qualname='...',
    type=<mixed-in class>,
    start=1,
    )
```

value

What the new enum class will record as its name.

names

The enum members. This can be a whitespace- or comma-separated string (values will start at 1 unless otherwise specified):

```
'RED GREEN BLUE' | 'RED,GREEN,BLUE' | 'RE
```

or an iterator of names:

```
['RED', 'GREEN', 'BLUE']
```

or an iterator of (name, value) pairs:

```
[('CYAN', 4), ('MAGENTA', 5), ('YELLOW',
```

or a mapping:

```
{'CHARTREUSE': 7, 'SEA_GREEN': 11, 'ROSEM
```

module

name of module where new enum class can be found.

qualname

where in module new enum class can be found.

type

type to mix in to new enum class.

start

number to start counting at if only names are passed in.

Changed in version 3.5: The *start* parameter was added.

Derived Enumerations

IntEnum

The first variation of **Enum** that is provided is also a subclass of **int**. Members of an **IntEnum** can be compared to integers; by extension, integer enumerations of different types can also be compared to each other:

```
>>> from enum import IntEnum
```

```
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Request(IntEnum):
...     POST = 1
...     GET = 2
...
>>> Shape == 1
False
>>> Shape.CIRCLE == 1
True
>>> Shape.CIRCLE == Request.POST
True
```

However, they still can't be compared to standard **`Enum`** enumerations:

```
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...
>>> Shape.CIRCLE == Color.RED
False
```

`IntEnum` values behave like integers in other ways you'd expect:

```
>>> int(Shape.CIRCLE)
1
>>> ['a', 'b', 'c'][Shape.CIRCLE]
'b'
>>> [i for i in range(Shape.SQUARE)]
[0, 1]
```

StrEnum

The second variation of **Enum** that is provided is also a subclass of **str**. Members of a **StrEnum** can be compared to strings; by extension, string enumerations of different types can also be compared to each other.

New in version 3.11.

IntFlag

The next variation of **Enum** provided, **IntFlag**, is also based on **int**. The difference being **IntFlag** members can be combined using the bitwise operators (&, |, ^, ~) and the result is still an **IntFlag** member, if possible. Like **IntEnum**, **IntFlag** members are also integers and can be used wherever an **int** is used.

Note

Any operation on an **IntFlag** member besides the bit-wise operations will lose the **IntFlag** membership.

Bit-wise operations that result in invalid **IntFlag** values will lose the **IntFlag** membership. See **FlagBoundary** for details.

New in version 3.6.

Changed in version 3.11.

Sample **IntFlag** class:

```
>>> from enum import IntFlag
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...
>>> Perm.R | Perm.W
<Perm.R|W: 6>
>>> Perm.R + Perm.W
6
>>> RW = Perm.R | Perm.W
```

```
>>> Perm.R in RW
True
```

It is also possible to name the combinations:

```
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...     RWX = 7
>>> Perm.RWX
<Perm.RWX: 7>
>>> ~Perm.RWX
<Perm: 0>
>>> Perm(7)
<Perm.RWX: 7>
```

Note

Named combinations are considered aliases. Aliases do not show up during iteration, but can be returned from by-value lookups.

Changed in version 3.11.

Another important difference between **IntFlag** and **Enum** is that if no flags are set (the value is 0), its boolean evaluation is **False**:

```
>>> Perm.R & Perm.X
<Perm: 0>
>>> bool(Perm.R & Perm.X)
False
```

Because **IntFlag** members are also subclasses of **int** they can be combined with them (but may lose **IntFlag** membership:

```
>>> Perm.X | 4
<Perm.R|X: 5>

>>> Perm.X | 8
```

Note

The negation operator, `~`, always returns an **`IntFlag`** member with a positive value:

```
>>> (~Perm.X).value == (Perm.R|Perm.W).value == 6
True
```

`IntFlag` members can also be iterated over:

```
>>> list(RW)
[<Perm.R: 4>, <Perm.W: 2>]
```

New in version 3.11.

Flag

The last variation is **`Flag`**. Like **`IntFlag`**, **`Flag`** members can be combined using the bitwise operators (&, |, ^, ~). Unlike **`IntFlag`**, they cannot be combined with, nor compared against, any other **`Flag`** enumeration, nor **`int`**. While it is possible to specify the values directly it is recommended to use **`auto`** as the value and let **`Flag`** select an appropriate value.

New in version 3.6.

Like **`IntFlag`**, if a combination of **`Flag`** members results in no flags being set, the boolean evaluation is **`False`**:

```
>>> from enum import Flag, auto
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.RED & Color.GREEN
<Color: 0>
>>> bool(Color.RED & Color.GREEN)
```

```
False
```

Individual flags should have values that are powers of two (1, 2, 4, 8, ...), while combinations of flags will not:

```
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...     WHITE = RED | BLUE | GREEN
...
>>> Color.WHITE
<Color.WHITE: 7>
```

Giving a name to the "no flags set" condition does not change its boolean value:

```
>>> class Color(Flag):
...     BLACK = 0
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.BLACK
<Color.BLACK: 0>
>>> bool(Color.BLACK)
False
```

`Flag` members can also be iterated over:

```
>>> purple = Color.RED | Color.BLUE
>>> list(purple)
[<Color.RED: 1>, <Color.BLUE: 2>]
```

New in version 3.11.

Note

For the majority of new code, **`Enum`** and **`Flag`** are strongly recommended, since **`IntEnum`** and **`IntFlag`** break some

semantic promises of an enumeration (by being comparable to integers, and thus by transitivity to other unrelated enumerations). **`IntEnum`** and **`IntFlag`** should be used only in cases where **`Enum`** and **`Flag`** will not do; for example, when integer constants are replaced with enumerations, or for interoperability with other systems.

Others

While **`IntEnum`** is part of the **`enum`** module, it would be very simple to implement independently:

```
class IntEnum(int, Enum):
    pass
```

This demonstrates how similar derived enumerations can be defined; for example a **`FloatEnum`** that mixes in **`float`** instead of **`int`**.

Some rules:

1. When subclassing **`Enum`**, mix-in types must appear before **`Enum`** itself in the sequence of bases, as in the **`IntEnum`** example above.
2. Mix-in types must be subclassable. For example, **`bool`** and **`range`** are not subclassable and will throw an error during Enum creation if used as the mix-in type.
3. While **`Enum`** can have members of any type, once you mix in an additional type, all the members must have values of that type, e.g. **`int`** above. This restriction does not apply to mix-ins which only add methods and don't specify another type.
4. When another data type is mixed in, the **`value`** attribute is *not the same* as the enum member itself, although it is equivalent and will compare equal.
5. %-style formatting: `%s` and `%r` call the **`Enum`** class's **`__str__()`** and **`__repr__()`** respectively; other codes (such as `%i` or `%h` for IntEnum) treat the enum member as its mixed-in type.
6. Formatted string literals, **`str.format()`**, and **`format()`** will use the enum's **`__str__()`** method.

Note

Because **IntEnum**, **IntFlag**, and **StrEnum** are designed to be drop-in replacements for existing constants, their **__str__()** method has been reset to their data types **__str__()** method.

When to use __new__() vs. __init__()

__new__() must be used whenever you want to customize the actual value of the **Enum** member. Any other modifications may go in either **__new__()** or **__init__()**, with **__init__()** being preferred.

For example, if you want to pass several items to the constructor, but only want one of them to be the value:

```
>>> class Coordinate(bytes, Enum):
...     """
...     Coordinate with binary codes that can be indexed
...     """
...     def __new__(cls, value, label, unit):
...         obj = bytes.__new__(cls, [value])
...         obj._value_ = value
...         obj.label = label
...         obj.unit = unit
...         return obj
...     PX = (0, 'P.X', 'km')
...     PY = (1, 'P.Y', 'km')
...     VX = (2, 'V.X', 'km/s')
...     VY = (3, 'V.Y', 'km/s')
...

>>> print(Coordinate['PY'])
Coordinate.PY

>>> print(Coordinate(3))
Coordinate.VY
```

Finer Points

Supported `__dunder__` names

`__members__` is a read-only ordered mapping of `member_name:member` items. It is only available on the class.

`__new__()`, if specified, must create and return the enum members; it is also a very good idea to set the member's **`_value_`** appropriately. Once all the members are created it is no longer used.

Supported `_sunder_` names

- `_name_` – name of the member
- `_value_` – value of the member; can be set / modified in `__new__`
- `_missing_` – a lookup function used when a value is not found; may be overridden
- `_ignore_` – a list of names, either as a **`list`** or a **`str`**, that will not be transformed into members, and will be removed from the final class
- `_order_` – used in Python 2/3 code to ensure member order is consistent (class attribute, removed during class creation)
- `_generate_next_value_` – used by the Functional API and by **`auto`** to get an appropriate value for an enum member; may be overridden

Note

For standard **`Enum`** classes the next value chosen is the last value seen incremented by one.

For **`Flag`** classes the next value chosen will be the next highest power-of-two, regardless of the last value seen.

New in version 3.6: `_missing_`, `_order_`, `_generate_next_value_`

New in version 3.7: `_ignore_`

To help keep Python 2 / Python 3 code in sync an **`_order_`** attribute can be provided. It will be checked against the actual order of the enumeration and raise an error if the two do not match:

```
>>> class Color(Enum):
...     _order_ = 'RED GREEN BLUE'
...     RED = 1
...     BLUE = 3
...     GREEN = 2
...
Traceback (most recent call last):
...
TypeError: member order does not match _order_:
  ['RED', 'BLUE', 'GREEN']
  ['RED', 'GREEN', 'BLUE']
```

Note

In Python 2 code the **`_order_`** attribute is necessary as definition order is lost before it can be recorded.

_Private_names

Private names are not converted to enum members, but remain normal attributes.

Changed in version 3.11.

`Enum` member type

Enum members are instances of their enum class, and are normally accessed as `EnumClass.member`. In Python versions `3.5` to `3.10` you could access members from other members – this practice was discouraged, and in `3.11` **`Enum`** returns to not allowing it:

```
>>> class FieldTypes(Enum):
```

```
...     name = 0
...     value = 1
...     size = 2
...
>>> FieldTypes.value.size
Traceback (most recent call last):
...
AttributeError: <enum 'FieldTypes'> member has no attrib
```

Changed in version 3.5.

Changed in version 3.11.

Creating members that are mixed with other data types

When subclassing other data types, such as **int** or **str**, with an **Enum**, all values after the = are passed to that data type's constructor. For example:

```
>>> class MyEnum(IntEnum):       # help(int) -> int(x, ba
...     example = '11', 16       # so x='11' and base=16
...
>>> MyEnum.example.value         # and hex(11) is...
17
```

Boolean value of **Enum** classes and members

Enum classes that are mixed with non-**Enum** types (such as **int**, **str**, etc.) are evaluated according to the mixed-in type's rules; otherwise, all members evaluate as **True**. To make your own enum's boolean evaluation depend on the member's value add the following to your class:

```
def __bool__(self):
    return bool(self.value)
```

Plain **Enum** classes always evaluate as **True**.

Enum classes with methods

If you give your enum subclass extra methods, like the Planet class below, those methods will show up in a `dir()` of the member, but not of the class:

```
>>> dir(Planet)
['EARTH', 'JUPITER', 'MARS', 'MERCURY', 'NEPTUNE', 'SATU
>>> dir(Planet.EARTH)
['__class__', '__doc__', '__module__', 'mass', 'name', '
```

Combining members of `Flag`

Iterating over a combination of `Flag` members will only return the members that are comprised of a single bit:

```
>>> class Color(Flag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
...     MAGENTA = RED | BLUE
...     YELLOW = RED | GREEN
...     CYAN = GREEN | BLUE
...
>>> Color(3)  # named combination
<Color.YELLOW: 3>
>>> Color(7)      # not named combination
<Color.RED|GREEN|BLUE: 7>
```

`Flag` and `IntFlag` minutia

Using the following snippet for our examples:

```
>>> class Color(IntFlag):
...     BLACK = 0
...     RED = 1
...     GREEN = 2
...     BLUE = 4
...     PURPLE = RED | BLUE
...     WHITE = RED | GREEN | BLUE
...
```

the following are true:

- single-bit flags are canonical
- multi-bit and zero-bit flags are aliases
- only canonical flags are returned during iteration:

```
>>> list(Color.WHITE)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

- negating a flag or flag set returns a new flag/flag set with the corresponding positive integer value:

```
>>> Color.BLUE
<Color.BLUE: 4>

>>> ~Color.BLUE
<Color.RED|GREEN: 3>
```

- names of pseudo-flags are constructed from their members' names:

```
>>> (Color.RED | Color.GREEN).name
'RED|GREEN'
```

- multi-bit flags, aka aliases, can be returned from operations:

```
>>> Color.RED | Color.BLUE
<Color.PURPLE: 5>

>>> Color(7)  # or Color(-1)
<Color.WHITE: 7>

>>> Color(0)
<Color.BLACK: 0>
```

- membership / containment checking: zero-valued flags are always considered to be contained:

```
>>> Color.BLACK in Color.WHITE
```

```
True
```

otherwise, only if all bits of one flag are in the other flag will True be returned:

```
>>> Color.PURPLE in Color.WHITE
True

>>> Color.GREEN in Color.PURPLE
False
```

There is a new boundary mechanism that controls how out-of-range / invalid bits are handled: `STRICT`, `CONFORM`, `EJECT`, and `KEEP`:

- STRICT –> raises an exception when presented with invalid values
- CONFORM –> discards any invalid bits
- EJECT –> lose Flag status and become a normal int with the given value

- KEEP –> keep the extra bits
  - keeps Flag status and extra bits
  - extra bits do not show up in iteration
  - extra bits do show up in repr() and str()

The default for Flag is `STRICT`, the default for `IntFlag` is `EJECT`, and the default for `_convert_` is `KEEP` (see `ssl.Options` for an example of when `KEEP` is needed).

How are Enums and Flags different?

Enums have a custom metaclass that affects many aspects of both derived **`Enum`** classes and their instances (members).

Enum Classes

The **`EnumType`** metaclass is responsible for providing the **`__contains__()`**, **`__dir__()`**, **`__iter__()`** and other methods

that allow one to do things with an **Enum** class that fail on a typical class, such as `list(Color)` or `some_enum_var in Color`. **EnumType** is responsible for ensuring that various other methods on the final **Enum** class are correct (such as **__new__()**, **__getnewargs__()**, **__str__()** and **__repr__()**).

Flag Classes

Flags have an expanded view of aliasing: to be canonical, the value of a flag needs to be a power-of-two value, and not a duplicate name. So, in addition to the **Enum** definition of alias, a flag with no value (a.k.a. `0`) or with more than one power-of-two value (e.g. `3`) is considered an alias.

Enum Members (aka instances)

The most interesting thing about enum members is that they are singletons. **EnumType** creates them all while it is creating the enum class itself, and then puts a custom **__new__()** in place to ensure that no new ones are ever instantiated by returning only the existing member instances.

Flag Members

Flag members can be iterated over just like the **Flag** class, and only the canonical members will be returned. For example:

```
>>> list(Color)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

(Note that `BLACK`, `PURPLE`, and `WHITE` do not show up.)

Inverting a flag member returns the corresponding positive value, rather than a negative value — for example:

```
>>> ~Color.RED
<Color.GREEN|BLUE: 6>
```

Flag members have a length corresponding to the number of power-of-two values they contain. For example:

```
>>> len(Color.PURPLE)
2
```

Enum Cookbook

While **Enum**, **IntEnum**, **StrEnum**, **Flag**, and **IntFlag** are expected to cover the majority of use-cases, they cannot cover them all. Here are recipes for some different types of enumerations that can be used directly, or as examples for creating one's own.

Omitting values

In many use-cases, one doesn't care what the actual value of an enumeration is. There are several ways to define this type of simple enumeration:

- use instances of **auto** for the value
- use instances of **object** as the value
- use a descriptive string as the value
- use a tuple as the value and a custom **__new__()** to replace the tuple with an **int** value

Using any of these methods signifies to the user that these values are not important, and also enables one to add, remove, or reorder members without having to renumber the remaining members.

Using **auto**

Using **auto** would look like:

```
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.GREEN
<Color.GREEN: 3>
```

Using **object**

Using **`object`** would look like:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...
>>> Color.GREEN
<Color.GREEN: <object object at 0x...>>
```

This is also a good example of why you might want to write your own **`__repr__()`**:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...     def __repr__(self):
...         return "<%s.%s>" % (self.__class__.__name__,
...
>>> Color.GREEN
<Color.GREEN>
```

Using a descriptive string

Using a string as the value would look like:

```
>>> class Color(Enum):
...     RED = 'stop'
...     GREEN = 'go'
...     BLUE = 'too fast!'
...
>>> Color.GREEN
<Color.GREEN: 'go'>
```

Using a custom **`__new__()`**

Using an auto-numbering **`__new__()`** would look like:

```
>>> class AutoNumber(Enum):
...     def __new__(cls):
...         value = len(cls.__members__) + 1
...         obj = object.__new__(cls)
...         obj._value_ = value
...         return obj
...
>>> class Color(AutoNumber):
...     RED = ()
...     GREEN = ()
...     BLUE = ()
...
>>> Color.GREEN
<Color.GREEN: 2>
```

To make a more general purpose `AutoNumber`, add `*args` to the signature:

```
>>> class AutoNumber(Enum):
...     def __new__(cls, *args):      # this is the only
...         value = len(cls.__members__) + 1
...         obj = object.__new__(cls)
...         obj._value_ = value
...         return obj
...
```

Then when you inherit from `AutoNumber` you can write your own `__init__` to handle any extra arguments:

```
>>> class Swatch(AutoNumber):
...     def __init__(self, pantone='unknown'):
...         self.pantone = pantone
...     AUBURN = '3497'
...     SEA_GREEN = '1246'
...     BLEACHED_CORAL = () # New color, no Pantone code
...
>>> Swatch.SEA_GREEN
<Swatch.SEA_GREEN: 2>
>>> Swatch.SEA_GREEN.pantone
```

```
'1246'
>>> Swatch.BLEACHED_CORAL.pantone
'unknown'
```

Note

The **`__new__()`** method, if defined, is used during creation of the Enum members; it is then replaced by Enum's **`__new__()`** which is used after class creation for lookup of existing members.

OrderedEnum

An ordered enumeration that is not based on **`IntEnum`** and so maintains the normal **`Enum`** invariants (such as not being comparable to other enumerations):

```
>>> class OrderedEnum(Enum):
...     def __ge__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value >= other.value
...         return NotImplemented
...     def __gt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value > other.value
...         return NotImplemented
...     def __le__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value <= other.value
...         return NotImplemented
...     def __lt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value < other.value
...         return NotImplemented
...
>>> class Grade(OrderedEnum):
...     A = 5
...     B = 4
...     C = 3
```

```
...     D = 2
...     F = 1
...
>>> Grade.C < Grade.A
True
```

DuplicateFreeEnum

Raises an error if a duplicate member value is found instead of creating an alias:

```
>>> class DuplicateFreeEnum(Enum):
...     def __init__(self, *args):
...         cls = self.__class__
...         if any(self.value == e.value for e in cls):
...             a = self.name
...             e = cls(self.value).name
...             raise ValueError(
...                 "aliases not allowed in DuplicateFre
...                 % (a, e))
...
>>> class Color(DuplicateFreeEnum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
...     GRENE = 2
...
Traceback (most recent call last):
...
ValueError: aliases not allowed in DuplicateFreeEnum:  '
```

Note

This is a useful example for subclassing Enum to add or change other behaviors as well as disallowing aliases. If the only desired change is disallowing aliases, the **`unique()`** decorator can be used instead.

Planet

If **`__new__()`** or **`__init__()`** is defined, the value of the enum member will be passed to those methods:

```
>>> class Planet(Enum):
...     MERCURY = (3.303e+23, 2.4397e6)
...     VENUS   = (4.869e+24, 6.0518e6)
...     EARTH   = (5.976e+24, 6.37814e6)
...     MARS    = (6.421e+23, 3.3972e6)
...     JUPITER = (1.9e+27,   7.1492e7)
...     SATURN  = (5.688e+26, 6.0268e7)
...     URANUS  = (8.686e+25, 2.5559e7)
...     NEPTUNE = (1.024e+26, 2.4746e7)
...     def __init__(self, mass, radius):
...         self.mass = mass       # in kilograms
...         self.radius = radius   # in meters
...     @property
...     def surface_gravity(self):
...         # universal gravitational constant  (m3 kg-1
...         G = 6.67300E-11
...         return G * self.mass / (self.radius * self.r
...
>>> Planet.EARTH.value
(5.976e+24, 6378140.0)
>>> Planet.EARTH.surface_gravity
9.802652743337129
```

TimePeriod

An example to show the **`_ignore_`** attribute in use:

```
>>> from datetime import timedelta
>>> class Period(timedelta, Enum):
...     "different lengths of time"
...     _ignore_ = 'Period i'
...     Period = vars()
...     for i in range(367):
...         Period['day_%d' % i] = i
```

```
...
>>> list(Period)[:2]
[<Period.day_0: datetime.timedelta(0)>, <Period.day_1: d
>>> list(Period)[-2:]
[<Period.day_365: datetime.timedelta(days=365)>, <Period
```

Subclassing EnumType

While most enum needs can be met by customizing **`Enum`** subclasses, either with class decorators or custom functions, **`EnumType`** can be subclassed to provide a different Enum experience.

Functional Programming HOWTO

Author

A. M. Kuchling

Release

0.32

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as iterators and generators and relevant library modules such as `itertools` and `functools`.

Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section on Iterators.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you're most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.

- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don't force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don't have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren't visible in the function's return value. Functions that have no side effects at all are called **purely functional**. Avoiding side effects means not using data structures that get updated as a program runs; every function's output must only depend on its input.

Some languages are very strict about purity and don't even have assignment statements such as `a=3` or `c = a + b`, but it's difficult to avoid all side effects, such as printing to the screen or writing to a disk file. Another example is a call to the **`print()`** or **`time.sleep()`** function, neither of which returns a useful value. Both are called only for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won't go to the extreme of avoiding all I/O or all assignments; instead, they'll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won't modify global variables or have other side effects.

Functional programming can be considered the opposite of object-oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

Formal provability

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's

variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don't depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

Composability

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you'll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.

Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called iterable if you can

get an iterator for it.

You can experiment with the iteration interface manually:

```
>>> L = [1, 2, 3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()  # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
StopIteration
>>>
```

Python expects iterable objects in several different contexts, the most important being the **`for`** statement. In the statement `for X in Y`, Y must be an iterator or some object for which **`iter()`** can create an iterator. These two statements are equivalent:

```
for i in iter(obj):
    print(i)

for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the **`list()`** or **`tuple()`** constructor functions:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as **`max()`** and **`min()`** can take a single iterator argument and will return the largest or smallest element. The `"in"` and `"not in"` operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; **`max()`**, **`min()`** will never return, and if the element X never appears in the stream, the `"in"` and `"not in"` operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the **`__next__()`** method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling **`iter()`** on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May':
...      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov':
>>> for key in m:
...     print(key, m[key])
Jan 1
```

```
Feb 2
Mar 3
Apr 4
May 5
Jun 6
Jul 7
Aug 8
Sep 9
Oct 10
Nov 11
Dec 12
```

Note that starting with Python 3.7, dictionary iteration order is guaranteed to be the same as the insertion order. In earlier versions, the behaviour was unspecified and could vary between implementations.

Applying **`iter()`** to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the **`values()`** or **`items()`** methods to get an appropriate iterator.

The **`dict()`** constructor can accept an iterator that returns a finite stream of `(key, value)` tuples:

```
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US',
>>> dict(iter(L))
{'Italy': 'Rome', 'France': 'Paris', 'US': 'Washington D
```

Files also support iteration by calling the **`readline()`** method until there are no more lines in the file. This means you can read each line of a file like this:

```
for line in file:
    # do something for each line
    ...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:

```
>>> S = {2, 3, 5, 7, 11, 13}
```

```
>>> for i in S:
...     print(i)
2
3
5
7
11
13
```

Generator expressions and list comprehensions

Two common operations on an iterator's output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: "listcomps" and "genexps") are a concise notation for such operations, borrowed from the functional programming language Haskell (https://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```
>>> line_list = ['  line 1\n', 'line 2  \n', ' \n', '']

>>> # Generator expression -- returns iterator
>>> stripped_iter = (line.strip() for line in line_list)

>>> # List comprehension -- returns list
>>> stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an `"if"` condition:

```
>>> stripped_list = [line.strip() for line in line_list
...                  if line != ""]
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an

iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren't useful if you're working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses ("()") and list comprehensions are surrounded by square brackets ("[]"). Generator expressions have the form:

```
( expression for expr in sequence1
              if condition1
              for expr2 in sequence2
              if condition2
              for expr3 in sequence3
              ...
              if condition3
              for exprN in sequenceN
              if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements

from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```
for expr1 in sequence1:
    if not (condition1):
        continue   # Skip this element
    for expr2 in sequence2:
        if not (condition2):
            continue   # Skip this element
        ...
        for exprN in sequenceN:
            if not (conditionN):
                continue   # Skip this element

            # Output the value of
            # the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python's grammar, if `expression` is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```

Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You're doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren't thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here's the simplest example of a generator function:

```
>>> def generate_ints(N):
...     for i in range(N):
...         yield i
```

Any function containing a **`yield`** keyword is a generator function; this is detected by Python's bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's **`__next__()`** method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)
>>> gen
```

```
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in <module>
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a, b, c = generate_ints(3)`.

Inside a generator function, `return value` causes `StopIteration(value)` to be raised from the **`__next__()`** method. Once this happens, or the bottom of the function is reached, the procession of values ends and the generator cannot yield any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the **`__next__()`** method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, Lib/test/test_generators.py [https://github.com/python/cpython/tree/3.11/Lib/test/test_generators.py], contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```
# A recursive generator that generates Tree leaves in ir
def inorder(t):
    if t:
        for x in inorder(t.left):
```

```
            yield x

        yield t.label

        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. **`yield`** became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(**PEP 342** [https://peps.python.org/pep-0342/] explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val`

```
= (yield i) + 12.)
```

Values are sent into a generator by calling its **`send(value)`** method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular **`__next__()`** method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in <module>
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don't just use its value in expressions unless you're sure that the **`send()`** method will be the only method used

to resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(value)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator's execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

  If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).

Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence

```
f(iterA[0], iterB[0]), f(iterA[1], iterB[1]),
f(iterA[2], iterB[2]), ....

>>> def upper(s):
...     return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

`filter(predicate, iter)` returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A **predicate** is a function that returns the truth value of some condition; for use with **`filter()`**, the predicate must take a single value.

```
>>> def is_even(x):
...     return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]
```

This can also be written as a list comprehension:

```
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter, start=0)` counts off the elements in the iterable returning 2-tuples containing the count (from *start*) and each element.

```
>>> for item in enumerate(['subject', 'verb', 'object']):
...     print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The *key* and *reverse* arguments are passed through to the constructed list's **`sort()`** method.

```
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the Sorting HOW TO.)

The **`any(iter)`** and **`all(iter)`** built-ins look at the truth values of an iterable's contents. **`any()`** returns `True` if any element in the iterable is a true value, and **`all()`** returns `True` if all of the elements are true values:

```
>>> any([0, 1, 0])
True
>>> any([0, 0, 0])
False
>>> any([1, 1, 1])
True
>>> all([0, 1, 0])
False
>>> all([0, 0, 0])
```

```
False
>>> all([1, 1, 1])
True
```

`zip(iterA, iterB, ...)` takes one element from each iterable and returns them in a tuple:

```
zip(['a', 'b', 'c'], (1, 2, 3)) =>
  ('a', 1), ('b', 2), ('c', 3)
```

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is lazy evaluation [https://en.wikipedia.org/wiki/Lazy_evaluation].)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(['a', 'b'], (1, 2, 3)) =>
  ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't go on to use the iterators further because you risk skipping a discarded element.

The itertools module

The **`itertools`** module contains a number of commonly used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator's elements as function

arguments.
- Functions for selecting portions of an iterator's output.
- A function for grouping an iterator's output.

Creating new iterators

`itertools.count(start, step)` returns an infinite stream of evenly spaced values. You can optionally supply the starting number, which defaults to 0, and the interval between numbers, which defaults to 1:

```
itertools.count() =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
itertools.count(10, 5) =>
  10, 15, 20, 25, 30, 35, 40, 45, 50, 55, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```
itertools.cycle([1, 2, 3, 4, 5]) =>
  1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

`itertools.repeat(elem, [n])` returns the provided element *n* times, or returns the element endlessly if *n* is not provided.

```
itertools.repeat('abc') =>
  abc, abc, abc, abc, abc, abc, abc, abc, abc, abc, ...
itertools.repeat('abc', 5) =>
  abc, abc, abc, abc, abc
```

`itertools.chain(iterA, iterB, ...)` takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
```

```
  a, b, c, 1, 2, 3
```

`itertools.islice(iter, [start], stop, [step])` returns a stream that's a slice of the iterator. With a single *stop* argument, it will return the first *stop* elements. If you supply a starting index, you'll get *stop-start* elements, and if you supply a value for *step*, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for *start*, *stop*, or *step*.

```
itertools.islice(range(10), 8) =>
  0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
  2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
  2, 4, 6
```

`itertools.tee(iter, [n])` replicates an iterator; it returns *n* independent iterators that will all return the contents of the source iterator. If you don't supply a value for *n*, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
   iterA, iterB

where iterA ->
   0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and   iterB ->
   0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

Calling functions on elements

The **`operator`** module contains a set of functions corresponding to Python's operators. Some examples are **`operator.add(a, b)`** (adds two values), **`operator.ne(a, b)`** (same as `a != b`), and **`operator.attrgetter('id')`** (returns a callable that fetches

the `.id` attribute).

`itertools.starmap(func, iter)` assumes that the iterable will return a stream of tuples, and calls *func* using these tuples as the arguments:

```
itertools.starmap(os.path.join,
                  [('/bin', 'python'), ('/usr', 'bin', '
                   ('/usr', 'bin', 'perl'), ('/usr', 'bi
=>
  /bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/ru
```

Selecting elements

Another group of functions chooses a subset of an iterator's elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite of **`filter()`**, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
  1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10

itertools.takewhile(less_than_10, itertools.count()) =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>
  0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

`itertools.compress(data, selectors)` takes two iterators and returns only those elements of *data* for which the corresponding element of *selectors* is true, stopping whenever either one is exhausted:

```
itertools.compress([1, 2, 3, 4, 5], [True, True, False,
   1, 2, 5
```

Combinatoric functions

The **`itertools.combinations(iterable, r)`** returns an iterator giving all possible *r*-tuple combinations of the elements contained in *iterable*.

```
itertools.combinations([1, 2, 3, 4, 5], 2) =>
  (1, 2), (1, 3), (1, 4), (1, 5),
  (2, 3), (2, 4), (2, 5),
  (3, 4), (3, 5),
  (4, 5)

itertools.combinations([1, 2, 3, 4, 5], 3) =>
  (1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5),
  (2, 3, 4), (2, 3, 5), (2, 4, 5),
  (3, 4, 5)
```

The elements within each tuple remain in the same order as *iterable* returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function, **`itertools.permutations(iterable, r=None)`**, removes this constraint on the order, returning all possible arrangements of length *r*:

```
itertools.permutations([1, 2, 3, 4, 5], 2) =>
  (1, 2), (1, 3), (1, 4), (1, 5),
```

```
  (2, 1), (2, 3), (2, 4), (2, 5),
  (3, 1), (3, 2), (3, 4), (3, 5),
  (4, 1), (4, 2), (4, 3), (4, 5),
  (5, 1), (5, 2), (5, 3), (5, 4)

itertools.permutations([1, 2, 3, 4, 5]) =>
  (1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),
  ...
  (5, 4, 3, 2, 1)
```

If you don't supply a value for *r* the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don't require that the contents of *iterable* are unique:

```
itertools.permutations('aba', 3) =>
  ('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),
  ('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple `('a', 'a', 'b')` occurs twice, but the two 'a' strings came from different positions.

The **`itertools.combinations_with_replacement(iterable, r)`** function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is selected.

```
itertools.combinations_with_replacement([1, 2, 3, 4, 5],
  (1, 1), (1, 2), (1, 3), (1, 4), (1, 5),
  (2, 2), (2, 3), (2, 4), (2, 5),
  (3, 3), (3, 4), (3, 5),
  (4, 4), (4, 5),
  (5, 5)
```

Grouping elements

The last function I'll discuss, **`itertools.groupby(iter, key_func=None)`**, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```
city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('T
             ...
            ]

def get_state(city_state):
    return city_state[1]

itertools.groupby(city_list, get_state) =>
  ('AL', iterator-1),
  ('AK', iterator-2),
  ('AZ', iterator-3), ...

where
iterator-1 =>
  ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL
iterator-2 =>
  ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
  ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ
```

`groupby()` assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.

The functools module

The **functools** module contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called "partial function application".

The constructor for **partial()** takes the arguments `(function, arg1, arg2, ..., kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified
    print('%s: %s' % (subsystem, message))
    ...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

functools.reduce(func, iter, [initial_value]) cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. *func* must be a function that takes two elements and returns a single value. **functools.reduce()** takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a **TypeError** exception is raised. If the initial value is supplied, it's used as a starting point and

`func(initial_value, A)` is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> functools.reduce(operator.concat, [])
Traceback (most recent call last):
  ...
TypeError: reduce() of empty sequence with no initial va
>>> functools.reduce(operator.mul, [1, 2, 3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use **`operator.add()`** with **`functools.reduce()`**, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called **`sum()`** to compute it:

```
>>> import functools, operator
>>> functools.reduce(operator.add, [1, 2, 3, 4], 0)
10
>>> sum([1, 2, 3, 4])
10
>>> sum([])
0
```

For many uses of **`functools.reduce()`**, though, it can be clearer to just write the obvious **`for`** loop:

```
import functools
# Instead of:
product = functools.reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

A related function is **`itertools.accumulate(iterable, func=operator.add)`**. It performs the same calculation, but

instead of returning only the final result, **`accumulate()`** returns an iterator that also yields each partial result:

```
itertools.accumulate([1, 2, 3, 4, 5]) =>
  1, 3, 6, 10, 15

itertools.accumulate([1, 2, 3, 4, 5], operator.mul) =>
  1, 2, 6, 24, 120
```

The operator module

The **`operator`** module was mentioned earlier. It contains a set of functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.

Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the **`lambda`** expression. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```
adder = lambda x, y: x+y

print_assign = lambda name, value: name + '=' + str(valu
```

An alternative is to just use the `def` statement and define a function in the usual way:

```
def adder(x, y):
    return x + y

def print_assign(name, value):
    return name + '=' + str(value)
```

Which alternative is preferable? That's a style question; my usual course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```
import functools
total = functools.reduce(lambda a, b: (0, a[1] + b[1]),
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```
import functools
def combine(a, b):
    return 0, a[1] + b[1]
```

```
total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```
total = 0
for a, b in items:
    total += b
```

Or the **`sum()`** built-in and a generator expression:

```
total = sum(b for a, b in items)
```

Many uses of **`functools.reduce()`** are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you're free to disagree about whether this lambda-free style is better.

Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp

sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

Author

Vinay Sajip <vinay_sajip at red-dove dot com>

Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software's developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the *level* or *severity*.

When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

Task you want to perform	The best tool for the task
Display console output for ordinary usage of a command line script or program	`print()`
Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)	`logging.info()` (or `logging.debug()` for very detailed output for diagnostic purposes)
Issue a warning regarding a particular runtime event	`warnings.warn()` if the issue is avoidable and the client application should be modified to eliminate the warning `logging.warning()` if there is nothing the client application can do about the situation, but the event should still be noted
Report suppression of an error without raising an exception (e.g. error handler in a long-running server process)	`logging.error()`, `logging.exception()` or `logging.critical()` as appropriate for the specific error and application domain

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

Level	When it's used
`DEBUG`	Detailed information, typically of interest only when diagnosing problems.
`INFO`	Confirmation that things are working as expected.
`WARNING`	An indication that something unexpected happened, or indicative of some problem in the near future (e.g. 'disk space low'). The software is still working as expected.
`ERROR`	Due to a more serious problem, the software has not been able to perform some function.
`CRITICAL`	A serious error, indicating that the program itself may be unable to continue running.

The default level is `WARNING`, which means that only events of this

level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

A simple example

A very simple example is:

```
import logging
logging.warning('Watch out!')  # will print a message to
logging.info('I told you so')  # will not print anything
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn't appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. 'Watch out!'. Don't worry about the 'root' part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

Logging to a file

A very common situation is that of recording logging events in a file, so let's look at that next. Be sure to try the following in a newly started Python interpreter, and don't just continue from the session described above:

```
import logging
logging.basicConfig(filename='example.log', encoding='ut
logging.debug('This message should go to the log file')
logging.info('So should this')
logging.warning('And this, too')
logging.error('And non-ASCII stuff, too, like Øresund ar
```

Changed in version 3.9: The *encoding* argument was added. In earlier Python versions, or if not specified, the encoding used is the default value used by **open()**. While not shown in the above example, an *errors* argument can also now be passed, which determines how encoding errors are handled. For available values and the default, see the documentation for **open()**.

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too
ERROR:root:And non-ASCII stuff, too, like Øresund and Ma
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to `DEBUG`, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable *loglevel*, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to **basicConfig()** via the *level* argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtaine
# command line argument. Convert to upper case to allow
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)
```

The call to `basicConfig()` should come *before* any calls to `debug()`, `info()`, etc. Otherwise, those functions will call `basicConfig()` for you with the default options. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file *example.log*. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the *filemode* argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode='w'
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```
# myapp.py
import logging
import mylib

def main():
    logging.basicConfig(filename='myapp.log', level=logg
    logging.info('Started')
    mylib.do_something()
    logging.info('Finished')

if __name__ == '__main__':
    main()

# mylib.py
import logging

def do_something():
    logging.info('Doing something')
```

If you run *myapp.py*, you should see this in *myapp.log*:

```
INFO:root:Started
INFO:root:Doing something
INFO:root:Finished
```

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in *mylib.py*. Note that for this simple usage pattern, you won't know, by looking in the log file, *where* in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you'll need to refer to the documentation beyond the tutorial level – see Advanced Logging Tutorial.

Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

```
import logging
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as **`str.format()`** and **`string.Template`**. These newer formatting options *are* supported, but exploring them is outside the scope of this tutorial: see Using particular formatting styles throughout your application for more information.

Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```
import logging
```

```
logging.basicConfig(format='%(levelname)s:%(message)s',
logging.debug('This message should appear on the console
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```

Notice that the 'root' which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for LogRecord attributes, but for simple usage, you just need the *levelname* (severity), *message* (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

Displaying the date/time in messages

To display the date and time of an event, you would place '%(asctime)s' in your format string:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s')
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is like ISO8601 or **RFC 3339** [https://datatracker.ietf.org/doc/html/rfc3339.html]. If you need more control over the formatting of the date/time, provide a *datefmt* argument to `basicConfig`, as in this example:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s', da
logging.warning('is when this event was logged.')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the *datefmt* argument is the same as supported by **`time.strftime()`**.

Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the comp.lang.python Usenet group (available at https://groups.google.com/forum/#!forum/comp.lang.python) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the Logging Cookbook.

Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a **`LogRecord`** instance.

Logging is performed by calling methods on instances of the **`Logger`** class (hereafter called *loggers*). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named 'scan' is the parent of loggers 'scan.text', 'scan.html' and 'scan.pdf'. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it's intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That's the logger used by the functions **`debug()`**, **`info()`**, **`warning()`**, **`error()`** and **`critical()`**, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger's name is printed as 'root' in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by *handler* classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using **`basicConfig()`** as in the tutorial examples. If you call the functions **`debug()`**, **`info()`**, **`warning()`**, **`error()`** and **`critical()`**, they will check to see if no destination is set; and if one is not set, they will set a destination of the console

(`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by **`basicConfig()`** for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to **`basicConfig()`** with the *format* keyword argument. For all options regarding how a format string is constructed, see Formatter Objects.

Logging Flow

The flow of log event information in loggers and handlers is illustrated in the following diagram.

Loggers

`Logger` objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

These are the most common configuration methods:

- **`Logger.setLevel()`** specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- **`Logger.addHandler()`** and **`Logger.removeHandler()`** add and remove handler objects from the logger object. Handlers are covered in more detail in Handlers.
- **`Logger.addFilter()`** and **`Logger.removeFilter()`**

add and remove filter objects from the logger object. Filters are covered in more detail in Filter Objects.

You don't need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- **`Logger.debug()`**, **`Logger.info()`**, **`Logger.warning()`**, **`Logger.error()`**, and **`Logger.critical()`** all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- **`Logger.exception()`** creates a log message similar to **`Logger.error()`**. The difference is that **`Logger.exception()`** dumps a stack trace along with it. Call this method only from an exception handler.
- **`Logger.log()`** takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to **`getLogger()`** with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective

level. If the parent has no explicit level set, *its* parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (`WARNING` by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger's handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the *propagate* attribute of a logger to `False`.)

Handlers

`Handler` objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. **`Logger`** objects can add zero or more handler objects to themselves with an **`addHandler()`** method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see Useful Handlers); the tutorials use mainly **`StreamHandler`** and **`FileHandler`** in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The **`setLevel()`** method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two **`setLevel()`** methods? The level set in the logger determines which severity of messages

it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- **`setFormatter()`** selects a Formatter object for this handler to use.
- **`addFilter()`** and **`removeFilter()`** respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of **`Handler`**. Instead, the **`Handler`** class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base **`logging.Handler`** class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

logging.Formatter._init_(*fmt=None*, *datefmt=None*, *style='%'*)

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `'%'`, `'{'`, or `'$'`. If one of these is not specified, then `'%'` will be used.

If the `style` is `'%'`, the message format string uses `%(<dictionary key>)s` styled string substitution; the possible keys are documented in LogRecord attributes. If the style is `'{'`, the message format string is assumed to be compatible with **`str.format()`** (using keyword arguments), while if the style is `'$'` then the message format string should conform to what is expected by **`string.Template.substitute()`**.

Changed in version 3.2: Added the `style` parameter.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
'%(asctime)s - %(levelname)s - %(message)s'
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, **`time.localtime()`** is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as **`time.localtime()`** or **`time.gmtime()`**. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the Formatter class (to `time.gmtime` for GMT display).

Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the **`fileConfig()`** function.
3. Creating a dictionary of configuration information and passing it to the **`dictConfig()`** function.

For the reference documentation on the last two options, see Configuration functions. The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```
import logging

# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
```

```
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s -

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug
2005-03-19 15:10:26,620 - simple_example - INFO - info m
2005-03-19 15:10:26,695 - simple_example - WARNING - war
2005-03-19 15:10:26,697 - simple_example - ERROR - error
2005-03-19 15:10:26,773 - simple_example - CRITICAL - cr
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:

```
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
```

```
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(messag
```

The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug
2005-03-19 15:38:55,979 - simpleExample - INFO - info me
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn
2005-03-19 15:38:56,055 - simpleExample - ERROR - error
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - cri
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

Warning

The **`fileConfig()`** function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any non-root loggers existing before the **`fileConfig()`** call to be disabled unless they (or an ancestor) are explicitly named in the configuration. Please refer to the reference documentation for more information, and specify `False` for this parameter if you wish.

The dictionary passed to **`dictConfig()`** can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as `True`. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of `False`.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either **`WatchedFileHandler`** (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```
version: 1
formatters:
  simple:
    format: '%(asctime)s - %(name)s - %(levelname)s - %(
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see Configuration functions.

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.

For versions of Python prior to 3.2, the behaviour is as follows:

- If *logging.raiseExceptions* is `False` (production mode), the event is silently dropped.
- If *logging.raiseExceptions* is `True` (development mode), a message 'No handlers could be found for logger X.Y.Z' is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a 'handler of last resort', stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a **`StreamHandler`** which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler's level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.

If for some reason you *don't* want these messages printed in the absence of any logging configuration, you can attach a do-nothing

handler to the top-level logger for your library. This avoids the message being printed, since a handler will always be found for the library's events: it just doesn't produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: **`NullHandler`** (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (*if* you want to prevent your library's logged events being output to `sys.stderr` in the absence of logging configuration). If all logging by a library *foo* is done using loggers with names matching 'foo.x', 'foo.x.y', etc. then the code:

```
import logging
logging.getLogger('foo').addHandler(logging.NullHandler(
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be 'orgname.foo' rather than just 'foo'.

Note

It is strongly advised that you *do not log to the root logger* in your library. Instead, use a logger with a unique and easily identifiable name, such as the `__name__` for your library's top-level package or module. Logging to the root logger will make it difficult or impossible for the application developer to configure the logging verbosity or handlers of your library as they wish.

Note

It is strongly advised that you *do not add any handlers other than* **`NullHandler`** *to your library's loggers*. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most

appropriate for their application: if you add handlers 'under the hood', you might well interfere with their ability to carry out unit tests and deliver logs which suit their requirements.

Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

Level	Numeric value
CRITICAL	50
ERROR	40
WARNING	30
INFO	20
DEBUG	10
NOTSET	0

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the **`LogRecord`** class. When a logger decides to actually log an event, a **`LogRecord`** instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of *handlers*, which are instances of subclasses of the **`Handler`** class. Handlers are responsible for ensuring that a logged message (in the form of a **`LogRecord`**) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed **`LogRecord`** instances intended for particular destinations. Each logger can have

zero, one or more handlers associated with it (via the `addHandler()` method of `Logger`). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the *propagate* flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of `Handler` will need to override this `emit()`.

Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly *a very bad idea to define custom levels if you are developing a library*. That's because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean different things for different libraries.

Useful Handlers

In addition to the base `Handler` class, many useful subclasses are provided:

1. `StreamHandler` instances send messages to streams (file-like objects).
2. `FileHandler` instances send messages to disk files.
3. `BaseRotatingHandler` is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.
4. `RotatingFileHandler` instances send messages to disk

files, with support for maximum log file sizes and log file rotation.

5. **`TimedRotatingFileHandler`** instances send messages to disk files, rotating the log file at certain timed intervals.
6. **`SocketHandler`** instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. **`DatagramHandler`** instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. **`SMTPHandler`** instances send messages to a designated email address.
9. **`SysLogHandler`** instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. **`NTEventLogHandler`** instances send messages to a Windows NT/2000/XP event log.
11. **`MemoryHandler`** instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **`HTTPHandler`** instances send messages to an HTTP server using either `GET` or `POST` semantics.
13. **`WatchedFileHandler`** instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.
14. **`QueueHandler`** instances send messages to a queue, such as those implemented in the **`queue`** or **`multiprocessing`** modules.
15. **`NullHandler`** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the 'No handlers could be found for logger XXX' message which can be displayed if the library user has not configured logging. See Configuring Logging for a Library for more information.

New in version 3.1: The **`NullHandler`** class.

New in version 3.2: The **`QueueHandler`** class.

The **`NullHandler`**, **`StreamHandler`** and **`FileHandler`** classes are defined in the core logging package. The other handlers are defined in a sub-module, **`logging.handlers`**. (There is also

another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the `Formatter` class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of **`BufferingFormatter`** can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of `Filter` can be added to both `Logger` and `Handler` instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic `Filter` functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler` checks to see if a module-level variable, **`raiseExceptions`**, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

Note

The default value of **raiseExceptions** is `True`. This is because during development, you typically want to be notified of any exceptions that occur. It's advised that you set **raiseExceptions** to `False` for production usage.

Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its **__str__()** method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the **SocketHandler** emits an event by pickling it and sending it over the wire.

Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the **isEnabledFor()** method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1(
                                        expensive_func2(
```

so that if the logger's threshold is set above `DEBUG`, the calls to **expensive_func1()** and **expensive_func2()** are never made.

Note

In some cases, **isEnabledFor()** can itself be more expensive

than you'd like (e.g. for deeply nested loggers where an explicit level is only set high up in the logger hierarchy). In such cases (or if you want to avoid calling a method in tight loops), you can cache the result of a call to `isEnabledFor()` in a local or instance variable, and use that instead of calling the method each time. Such a cached value would only need to be recomputed when the logging configuration changes dynamically while the application is running (which is not all that common).

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

What you don't want to collect	How to avoid collecting it
Information about where calls were made from.	Set `logging._srcfile` to `None`. This avoids calling `sys._getframe()`, which may help to speed up your code in environments like PyPy (which can't speed up code that uses `sys._getframe()`).
Threading information.	Set `logging.logThreads` to `False`.
Current process ID (`os.getpid()`)	Set `logging.logProcesses` to `False`.
Current process name when using `multiprocessing` to manage multiple processes.	Set `logging.logMultiprocessing` to `False`.

Also note that the core logging module only includes the basic handlers. If you don't import `logging.handlers` and `logging.config`, they won't take up any memory.

A logging cookbook

Logging Cookbook

Author

Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past. For links to tutorial and reference information, please see Other resources.

Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s -
```

```
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Au
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Aux
logger.info('calling auxiliary_module.Auxiliary.do_somet
a.do_something()
logger.info('finished auxiliary_module.Auxiliary.do_some
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()'
```

Here is the auxiliary module:

```
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxi

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_applicatio
        self.logger.info('creating an instance of Auxili

    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_functio
```

The output looks like this:

```
2005-03-23 23:47:11,663 - spam_application - INFO -
```

```
   creating an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,665 - spam_application.auxiliary.Aux
   creating an instance of Auxiliary
2005-03-23 23:47:11,665 - spam_application - INFO -
   created an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,668 - spam_application - INFO -
   calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary.Aux
   doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary.Aux
   done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
   finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -

   received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
   done with auxiliary_module.some_function()
```

Logging from multiple threads

Logging from multiple threads requires no special effort. The following example shows logging from the main (initial) thread and another thread:

```
import logging
import threading
import time

def worker(arg):
    while not arg['stop']:
        logging.debug('Hi from myfunc')
        time.sleep(0.5)

def main():
    logging.basicConfig(level=logging.DEBUG, format='%(r
    info = {'stop': False}
```

```
    thread = threading.Thread(target=worker, args=(info,
    thread.start()
    while True:
        try:
            logging.debug('Hello from main')
            time.sleep(0.75)
        except KeyboardInterrupt:
            info['stop'] = True
            break
    thread.join()

if __name__ == '__main__':
    main()
```

When run, the script should print something like the following:

```
   0 Thread-1 Hi from myfunc
   3 MainThread Hello from main
 505 Thread-1 Hi from myfunc
 755 MainThread Hello from main
1007 Thread-1 Hi from myfunc
1507 MainThread Hello from main
1508 Thread-1 Hi from myfunc
2010 Thread-1 Hi from myfunc
2258 MainThread Hello from main
2512 Thread-1 Hi from myfunc
3009 MainThread Hello from main
3013 Thread-1 Hi from myfunc
3515 Thread-1 Hi from myfunc
3761 MainThread Hello from main
4017 Thread-1 Hi from myfunc
4513 MainThread Hello from main
4518 Thread-1 Hi from myfunc
```

This shows the logging output interspersed as one might expect. This approach works for more threads than shown here, of course.

Multiple handlers and formatters

Loggers are plain Python objects. The **`addHandler()`** method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s -
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named *fh*.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`: Unlike the print statements, which you will have to delete or comment out later, the logger.debug statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```
import logging

# set up logging to file - see previous section for more
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(name)-12s %(le
                    datefmt='%m-%d %H:%M',
                    filename='/tmp/myapp.log',
                    filemode='w')
# define a Handler which writes INFO messages or higher
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logge
logging.info('Jackdaws love my big sphinx of quartz.')
```

```
# Now, define a couple of other loggers which might repr
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from q
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see

```
root        : INFO     Jackdaws love my big sphinx of qu
myapp.area1 : INFO     How quickly daft jumping zebras v
myapp.area2 : WARNING  Jail zesty vixen who grabbed pay
myapp.area2 : ERROR    The five boxing wizards jump quic
```

and in the file you will see something like

```
10-22 22:19 root         INFO     Jackdaws love my big s
10-22 22:19 myapp.area1  DEBUG    Quick zephyrs blow, ve
10-22 22:19 myapp.area1  INFO     How quickly daft jumpi
10-22 22:19 myapp.area2  WARNING  Jail zesty vixen who g
10-22 22:19 myapp.area2  ERROR    The five boxing wizard
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.

Note that the above choice of log filename `/tmp/myapp.log` implies use of a standard location for temporary files on POSIX systems. On Windows, you may need to choose a different directory name for the log - just ensure that the directory exists and that you have the permissions to create and update files in it.

Custom handling of levels

Sometimes, you might want to do something slightly different from the standard handling of levels in handlers, where all levels above a threshold get processed by a handler. To do this, you need to use filters. Let's look at a scenario where you want to arrange things as follows:

- Send messages of severity `INFO` and `WARNING` to `sys.stdout`
- Send messages of severity `ERROR` and above to `sys.stderr`
- Send messages of severity `DEBUG` and above to file `app.log`

Suppose you configure logging with the following JSON:

```
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "handlers": {
        "stdout": {
            "class": "logging.StreamHandler",
            "level": "INFO",
            "formatter": "simple",
            "stream": "ext://sys.stdout",
        },
        "stderr": {
            "class": "logging.StreamHandler",
            "level": "ERROR",
            "formatter": "simple",
            "stream": "ext://sys.stderr"
        },
        "file": {
            "class": "logging.FileHandler",
            "formatter": "simple",
            "filename": "app.log",
```

```
            "mode": "w"
        }
    },
    "root": {
        "level": "DEBUG",
        "handlers": [
            "stderr",
            "stdout",
            "file"
        ]
    }
}
```

This configuration does *almost* what we want, except that `sys.stdout` would show messages of severity `ERROR` and above as well as `INFO` and `WARNING` messages. To prevent this, we can set up a filter which excludes those messages and add it to the relevant handler. This can be configured by adding a `filters` section parallel to `formatters` and `handlers`:

```
"filters": {
    "warnings_and_below": {
        "()" : "__main__.filter_maker",
        "level": "WARNING"
    }
}
```

and changing the section on the `stdout` handler to add it:

```
"stdout": {
    "class": "logging.StreamHandler",
    "level": "INFO",
    "formatter": "simple",
    "stream": "ext://sys.stdout",
    "filters": ["warnings_and_below"]
}
```

A filter is just a function, so we can define the `filter_maker` (a factory function) as follows:

```
def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter
```

This converts the string argument passed in to a numeric level, and returns a function which only returns `True` if the level of the passed in record is at or below the specified level. Note that in this example I have defined the `filter_maker` in a test script `main.py` that I run from the command line, so its module will be `__main__` - hence the `__main__.filter_maker` in the filter configuration. You will need to change that if you define it in a different module.

With the filter added, we can run `main.py`, which in full is:

```
import json
import logging
import logging.config

CONFIG = '''
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
            "level": "WARNING"
        }
    },
    "handlers": {
```

```
        "stdout": {
            "class": "logging.StreamHandler",
            "level": "INFO",
            "formatter": "simple",
            "stream": "ext://sys.stdout",
            "filters": ["warnings_and_below"]
        },
        "stderr": {
            "class": "logging.StreamHandler",
            "level": "ERROR",
            "formatter": "simple",
            "stream": "ext://sys.stderr"
        },
        "file": {
            "class": "logging.FileHandler",
            "formatter": "simple",
            "filename": "app.log",
            "mode": "w"
        }
    },
    "root": {
        "level": "DEBUG",
        "handlers": [
            "stderr",
            "stdout",
            "file"
        ]
    }
}
'''

def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter
```

```
logging.config.dictConfig(json.loads(CONFIG))
logging.debug('A DEBUG message')
logging.info('An INFO message')
logging.warning('A WARNING message')
logging.error('An ERROR message')
logging.critical('A CRITICAL message')
```

And after running it like this:

```
python main.py 2>stderr.log >stdout.log
```

We can see the results are as expected:

```
$ more *.log
::::::::::::::
app.log
::::::::::::::
DEBUG    - A DEBUG message
INFO     - An INFO message
WARNING  - A WARNING message
ERROR    - An ERROR message
CRITICAL - A CRITICAL message
::::::::::::::
stderr.log
::::::::::::::
ERROR    - An ERROR message
CRITICAL - A CRITICAL message
::::::::::::::
stdout.log
::::::::::::::
INFO     - An INFO message
WARNING  - A WARNING message
```

Configuration server example

Here is an example of a module using the logging configuration server:

```
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warning('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```
#!/usr/bin/env python
import socket, sys, struct

with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()
```

```
HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```

Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the **`SMTPHandler`**: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a **`SocketHandler`** operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a **`QueueHandler`** to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the **`queue.Full`** exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only `QueueHandlers` to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is **`QueueListener`**, which has

been designed as the counterpart to **`QueueHandler`**. A **`QueueListener`** is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for LogRecords sent from `QueueHandlers` (or any other source of `LogRecords`, for that matter). The `LogRecords` are removed from the queue and passed to the handlers for processing.

The advantage of having a separate **`QueueListener`** class is that you can use the same instance to service multiple `QueueHandlers`. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```
que = queue.Queue(-1)  # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated
# the event (the main thread) rather than the internal
# thread which monitors the internal queue. This is what
# you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

Note

Although the earlier discussion wasn't specifically talking about async code, but rather about slow logging handlers, it should be noted that when logging from async code, network and even file

handlers could lead to problems (blocking the event loop) because some logging is done from **asyncio** internals. It might be best, if any async code is used in an application, to use the above approach for logging, so that any blocking code runs only in the `QueueListener` thread.

Changed in version 3.5: Prior to Python 3.5, the **QueueListener** always passed every message received from the queue to every handler it was initialized with. (This was because it was assumed that level filtering was all done on the other side, where the queue is filled.) From 3.5 onwards, this behaviour can be changed by passing a keyword argument `respect_handler_level=True` to the listener's constructor. When this is done, the listener compares the level of each message with the handler's level, and only passes a message to a handler if it's appropriate to do so.

Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a **SocketHandler** instance to the root logger at the sending end:

```
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhos
                    logging.handlers.DEFAULT_TCP_LOGGING
# don't bother with a formatter, since a socket handler
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logge
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might repr
```

```
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from q
logger2.error('The five boxing wizards jump quickly.')
```

At the receiving end, you can set up a receiver using the **socketserver** module. Here is a basic working example:

```
import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestH
    """Handler for a streaming logging request.

    This basically logs the record using whatever loggin
    configured locally.
    """

    def handle(self):
        """
        Handle multiple requests - each expected to be a
        followed by the LogRecord in pickle format. Logs
        according to whatever policy is configured local
        """
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack('>L', chunk)[0]
            chunk = self.connection.recv(slen)
```

```
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(sle
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return pickle.loads(data)

    def handleLogRecord(self, record):
        # if a name is specified, we use the named logge
        # implied by the record.
        if self.server.logname is not None:
            name = self.server.logname
        else:
            name = record.name
        logger = logging.getLogger(name)
        # N.B. EVERY record gets logged. This is because
        # is normally called AFTER logger-level filterin
        # to do filtering, do it at the client end to sa
        # cycles and network bandwidth!
        logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPS
    """
    Simple TCP socket-based logging receiver suitable fo
    """

    allow_reuse_address = True

    def __init__(self, host='localhost',
                 port=logging.handlers.DEFAULT_TCP_LOGGI
                 handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, (
        self.abort = 0
        self.timeout = 1
        self.logname = None
```

```
    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.file
                                        [], [],
                                        self.timeout)
            if rd:
                self.handle_request()
            abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %(level
    tcpserver = LogRecordSocketReceiver()
    print('About to start TCP server...')
    tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()
```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```
About to start TCP server...
   59 root            INFO     Jackdaws love my big sphi
   59 myapp.area1     DEBUG    Quick zephyrs blow, vexir
   69 myapp.area1     INFO     How quickly daft jumping
   69 myapp.area2     WARNING  Jail zesty vixen who grab
   69 myapp.area2     ERROR    The five boxing wizards j
```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the **`makePickle()`** method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.

Running a logging socket listener in production

To run a logging listener in production, you may need to use a process-management tool such as Supervisor [http://supervisord.org/]. Here is a Gist [https://gist.github.com/vsajip/4b227eeec43817465ca835ca66f75e2b] which provides the bare-bones files to run the above functionality using Supervisor. It consists of the following files:

File	Purpose
`prepare.sh`	A Bash script to prepare the environment for testing
`supervisor.conf`	The Supervisor configuration file, which has entries for the listener and a multi-process web application
`ensure_app.sh`	A Bash script to ensure that Supervisor is running with the above configuration
`log_listener.py`	The socket listener program which receives log events and records them to a file
`main.py`	A simple web application which performs logging via a socket connected to the listener
`webapp.json`	A JSON configuration file for the web application
`client.py`	A Python script to exercise the web application

The web application uses Gunicorn [https://gunicorn.org/], which is a popular web application server that starts multiple worker processes to handle requests. This example setup shows how the workers can write to the same log file without conflicting with one another — they all go through the socket listener.

To test these files, do the following in a POSIX environment:

1. Download the Gist [https://gist.github.com/vsajip/4b227eeec43817465ca835ca66f75e2b] as a ZIP archive using the *Download ZIP* button.
2. Unzip the above files from the archive into a scratch directory.
3. In the scratch directory, run `bash prepare.sh` to get things ready. This creates a `run` subdirectory to contain Supervisor-related and log files, and a `venv` subdirectory to contain a virtual environment into which `bottle`, `gunicorn` and `supervisor` are installed.
4. Run `bash ensure_app.sh` to ensure that Supervisor is running with the above configuration.
5. Run `venv/bin/python client.py` to exercise the web

application, which will lead to records being written to the log.
6. Inspect the log files in the `run` subdirectory. You should see the most recent log lines in files matching the pattern `app.log*`. They won't be in any particular order, since they have been handled concurrently by different worker processes in a non-deterministic way.
7. You can shut down the listener and the web application by running `venv/bin/supervisorctl -c supervisor.conf shutdown`.

You may need to tweak the configuration files in the unlikely event that the configured ports clash with something else in your test environment.

Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the *extra* parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create **`Logger`** instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of **`Logger`** instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of **`Logger`** instances becomes effectively unbounded.

Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the **`LoggerAdapter`** class. This class is designed to look like a **`Logger`**, so that you can call **`debug()`**, **`info()`**, **`warning()`**,

error(), **exception()**, **critical()** and **log()**. These methods have the same signatures as their counterparts in **Logger**, so you can use the two types of instances interchangeably.

When you create an instance of **LoggerAdapter**, you pass it a **Logger** instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of **LoggerAdapter**, it delegates the call to the underlying instance of **Logger** passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of **LoggerAdapter**:

```
def debug(self, msg, /, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, afte
    contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The **process()** method of **LoggerAdapter** is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an 'extra' key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an 'extra' keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using 'extra' is that the values in the dict-like object are merged into the **LogRecord** instance's _dict_, allowing you to use customized strings with your **Formatter** instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass **LoggerAdapter** and override **process()** to do what you need. Here is a simple example:

```
class CustomAdapter(logging.LoggerAdapter):
```

```
    """
    This example adapter expects the passed in dict-like
    'connid' key, whose value in brackets is prepended t
    """
    def process(self, msg, kwargs):
        return '[%s] %s' % (self.extra['connid'], msg),
```

which you can use like this:

```
logger = logging.getLogger(__name__)
adapter = CustomAdapter(logger, {'connid': some_conn_id}
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

Using objects other than dicts to pass contextual information

You don't need to pass an actual dict to a **`LoggerAdapter`** - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined **`Filter`**. `Filter` instances are allowed to modify the `LogRecords` passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom **`Formatter`**.

For example in a web application, the request being processed (or at least, the interesting parts of it) can be stored in a threadlocal (**`threading.local`**) variable, and then accessed from a `Filter` to add, say, information from the request - say, the remote IP address and remote user's username - to the `LogRecord`, using the attribute names 'ip' and 'user' as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual informatio

    Rather than use actual contextual information, we ju
    data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1'

    def filter(self, record):

        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNI
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
    a1.addFilter(f)
    a2.addFilter(f)
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters'
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, 'A message at %s level with %d %s',
```

which, when run, produces something like:

```
2010-09-06 22:38:15,292 a.b.c DEBUG    IP: 123.231.231.1

```

Use of `contextvars`

Since Python 3.7, the **`contextvars`** module has provided context-local storage which works for both **`threading`** and **`asyncio`** processing needs. This type of storage may thus be generally preferable to thread-locals. The following example shows how, in a multi-threaded environment, logs can populated with contextual information such as, for example, request attributes handled by web applications.

For the purposes of illustration, say that you have different web applications, each independent of the other but running in the same Python process and using a library common to them. How can each of these applications have their own log, where all logging messages from the library (and other request processing code) are directed to the appropriate application's log file, while including in the log additional contextual information such as client IP, HTTP request method and client username?

Let's assume that the library can be simulated by the following code:

```
# webapplib.py
import logging
import time
```

```
logger = logging.getLogger(__name__)

def useful():
    # Just a representative event logged from the librar
    logger.debug('Hello from webapplib!')
    # Just sleep for a bit so other threads get to run
    time.sleep(0.01)
```

We can simulate the multiple web applications by means of two simple classes, `Request` and `WebApp`. These simulate how real threaded web applications work - each request is handled by a thread:

```
# main.py
import argparse
from contextvars import ContextVar
import logging
import os
from random import choice
import threading
import webapplib

logger = logging.getLogger(__name__)
root = logging.getLogger()
root.setLevel(logging.DEBUG)

class Request:
    """
    A simple dummy request class which just holds dummy
    client IP address and client username
    """
    def __init__(self, method, ip, user):
        self.method = method
        self.ip = ip
        self.user = user

# A dummy set of requests which will be used in the simu
# from this list randomly. Note that all GET requests ar
# addresses, whereas POST requests are from 192.16.3.XXX
```

```
# are represented in the sample requests.

REQUESTS = [
    Request('GET', '192.168.2.20', 'jim'),
    Request('POST', '192.168.3.20', 'fred'),
    Request('GET', '192.168.2.21', 'sheila'),
    Request('POST', '192.168.3.21', 'jim'),
    Request('GET', '192.168.2.22', 'fred'),
    Request('POST', '192.168.3.22', 'sheila'),
]

# Note that the format string includes references to req
# such as HTTP method, client IP and username

formatter = logging.Formatter('%(threadName)-11s %(appNa

# Create our context variables. These will be filled at
# processing, and used in the logging that happens durin

ctx_request = ContextVar('request')
ctx_appname = ContextVar('appname')

class InjectingFilter(logging.Filter):
    """
    A filter which injects context-specific information
    that only information for a specific webapp is inclu
    """
    def __init__(self, app):
        self.app = app

    def filter(self, record):
        request = ctx_request.get()
        record.method = request.method
        record.ip = request.ip
        record.user = request.user
        record.appName = appName = ctx_appname.get()
        return appName == self.app.name
```

```
class WebApp:
    """
    A dummy web application class which has its own hand
    webapp-specific log.
    """
    def __init__(self, name):
        self.name = name
        handler = logging.FileHandler(name + '.log', 'w'
        f = InjectingFilter(self)
        handler.setFormatter(formatter)
        handler.addFilter(f)
        root.addHandler(handler)
        self.num_requests = 0

    def process_request(self, request):
        """
        This is the dummy method for processing a reques
        different thread for every request. We store the
        the context vars before doing anything else.
        """
        ctx_request.set(request)
        ctx_appname.set(self.name)
        self.num_requests += 1
        logger.debug('Request processing started')
        webapplib.useful()
        logger.debug('Request processing finished')

def main():
    fn = os.path.splitext(os.path.basename(__file__))[0]
    adhf = argparse.ArgumentDefaultsHelpFormatter
    ap = argparse.ArgumentParser(formatter_class=adhf, p
                                 description='Simulate a
                                             'applicatio
                                             'requests,
                                             'context ca
                                             'populate l
    aa = ap.add_argument
    aa('--count', '-c', default=100, help='How many requ
```

```
    options = ap.parse_args()

    # Create the dummy webapps and put them in a list wh
    # from randomly
    app1 = WebApp('app1')
    app2 = WebApp('app2')
    apps = [app1, app2]
    threads = []
    # Add a common handler which will capture all events
    handler = logging.FileHandler('app.log', 'w')
    handler.setFormatter(formatter)
    root.addHandler(handler)

    # Generate calls to process requests
    for i in range(options.count):
        try:
            # Pick an app at random and a request for it
            app = choice(apps)
            request = choice(REQUESTS)
            # Process the request in its own thread
            t = threading.Thread(target=app.process_requ
            threads.append(t)
            t.start()
        except KeyboardInterrupt:
            break

    # Wait for the threads to terminate
    for t in threads:
        t.join()

    for app in apps:
        print('%s processed %s requests' % (app.name, ap

if __name__ == '__main__':
    main()
```

If you run the above, you should find that roughly half the requests go into `app1.log` and the rest into `app2.log`, and the all the requests are logged to `app.log`. Each webapp-specific log will

contain only log entries for only that webapp, and the request information will be displayed consistently in the log (i.e. the information in each dummy request will always appear together in a log line). This is illustrated by the following shell output:

```
~/logging-contextual-webapp$ python main.py
app1 processed 51 requests
app2 processed 49 requests
~/logging-contextual-webapp$ wc -l *.log
  153 app1.log
  147 app2.log

```

Imparting contextual information in handlers

Each **`Handler`** has its own chain of filters. If you want to add contextual information to a **`LogRecord`** without leaking it to other handlers, you can use a filter that returns a new **`LogRecord`** instead of modifying it in-place, as shown in the following script:

```
import copy
import logging

def filter(record: logging.LogRecord):
    record = copy.copy(record)
    record.user = 'jim'
    return record

if __name__ == '__main__':
    logger = logging.getLogger()
    logger.setLevel(logging.INFO)
    handler = logging.StreamHandler()
    formatter = logging.Formatter('%(message)s from %(us
    handler.setFormatter(formatter)
    handler.addFilter(filter)
    logger.addHandler(handler)

    logger.info('A log message')
```

Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process *is* supported, logging to a single file from *multiple processes* is *not* supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple

processes, one way of doing this is to have all the processes log to a **SocketHandler**, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) This section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

You could also write your own handler which uses the **Lock** class from the **multiprocessing** module to serialize access to the file from your processes. The existing **FileHandler** and subclasses do not make use of **multiprocessing** at present, though they may do so in the future. Note that at present, the **multiprocessing** module does not provide working lock functionality on all platforms (see https://bugs.python.org/issue3770).

Alternatively, you can use a `Queue` and a **QueueHandler** to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

#
# Because you'll want to define the logging configuratio
```

```
# listener and worker process functions take a configure
# for configuring logging for that process. These functi
# which they use for communication.
#
# In practice, you can configure the listener however yo
# simple example, the listener does not apply level or f
# In practice, you would probably want to do this logic
# sending events which would be filtered out between pro
#
# The size of the rotated files is made small so you can
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log
    f = logging.Formatter('%(asctime)s %(processName)-10
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for
# (LogRecords)on the queue and handle them, quit when yo
# LogRecord.
def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None:  # We send this as a sent
                break
            logger = logging.getLogger(record.name)
            logger.handle(record)  # No level or filter
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

LEVELS = [logging.DEBUG, logging.INFO, logging.WARNING,
          logging.ERROR, logging.CRITICAL]
```

```

# Note that on Windows you can't rely on fork semantics,
# will run the logging configuration code when it starts
def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue)  # Just the
    root = logging.getLogger()
    root.addHandler(h)
    # send all messages, for demo; no other level or fil
    root.setLevel(logging.DEBUG)

# This is the worker process top-level loop, which just
# random intervening delays before terminating.
# The print messages are just so you know it's doing som
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)

# Here's where the demo gets orchestrated. Create the qu
# the listener, create ten workers and start them, wait
# then send a None to the queue to tell the listener to
def main():
```

```
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_p
                                       args=(queue, list
    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_p
                                         args=(queue, wo
        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()
```

A variant of the above script keeps the logging in the main process, in a separate thread:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
```

```
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNI
              logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz',
               'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()
    d = {
        'version': 1,
        'formatters': {
            'detailed': {
                'class': 'logging.Formatter',
                'format': '%(asctime)s %(name)-15s %(lev
            }
        },

            'console': {
                'class': 'logging.StreamHandler',
                'level': 'INFO',
            },
            'file': {
                'class': 'logging.FileHandler',
                'filename': 'mplog.log',
                'mode': 'w',
                'formatter': 'detailed',
            },
            'foofile': {
                'class': 'logging.FileHandler',
                'filename': 'mplog-foo.log',
                'mode': 'w',
```

```
                'formatter': 'detailed',
            },
            'errors': {
                'class': 'logging.FileHandler',
                'filename': 'mplog-errors.log',
                'mode': 'w',
                'level': 'ERROR',
                'formatter': 'detailed',
            },
        },
        'loggers': {
            'foo': {
                'handlers': ['foofile']
            }
        },
        'root': {
            'level': 'DEBUG',
            'handlers': ['console', 'file', 'errors']
        },
    }
    workers = []
    for i in range(5):
        wp = Process(target=worker_process, name='worker
        workers.append(wp)
        wp.start()
    logging.config.dictConfig(d)
    lp = threading.Thread(target=logger_thread, args=(q,
    lp.start()
    # At this point, the main process could do some usef
    # Once it's done that, it can wait for the workers t
    for wp in workers:
        wp.join()
    # And now tell the logging thread to finish up, too
    q.put(None)
    lp.join()
```

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the `foo` logger has a special handler which stores all events in the `foo` subsystem in a file `mplog-foo.log`.

This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.

Using concurrent.futures.ProcessPoolExecutor

If you want to use `concurrent.futures.ProcessPoolExecutor` to start your worker processes, you need to create the queue slightly differently. Instead of

```
queue = multiprocessing.Queue(-1)
```

you should use

```
queue = multiprocessing.Manager().Queue(-1)  # also work
```

and you can then replace the worker creation from this:

```
workers = []
for i in range(10):
    worker = multiprocessing.Process(target=worker_proce
                                     args=(queue, worker
    workers.append(worker)
    worker.start()
for w in workers:
    w.join()
```

to this (remembering to first import `concurrent.futures`):

```
with concurrent.futures.ProcessPoolExecutor(max_workers=
    for i in range(10):
        executor.submit(worker_process, queue, worker_co
```

Deploying Web applications using Gunicorn and uWSGI

When deploying Web applications using Gunicorn [https://gunicorn.org/] or uWSGI [https://uwsgi-docs.readthedocs.io/en/latest/] (or similar), multiple worker processes are created to handle client

requests. In such environments, avoid creating file-based handlers directly in your web application. Instead, use a **`SocketHandler`** to log from the web application to a listener in a separate process. This can be set up using a process management tool such as Supervisor - see Running a logging socket listener in production for more details.

Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a **`RotatingFileHandler`**:

```
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
              LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)
```

```
for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5
```

The most current file is always `logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (`.1` becomes `.2`, etc.) and the `.6` file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set *maxBytes* to an appropriate value.

Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: **`string.Template`** (added in Python 2.4) and **`str.format()`** (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The **`Formatter`** class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to `'%'`, but other possible values are `'{'` and `'$'`, which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but by explicitly specifying a style parameter, you get the ability to specify format strings which work with **`str.format()`** or **`string.Template`**. Here's an example console session to show the

possibilities:

```
>>> import logging
>>> root = logging.getLogger()
>>> root.setLevel(logging.DEBUG)
>>> handler = logging.StreamHandler()
>>> bf = logging.Formatter('{asctime} {name} {levelname:
...                        style='{')
>>> handler.setFormatter(bf)
>>> root.addHandler(handler)
>>> logger = logging.getLogger('foo.bar')
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG    This is a DEBUG
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITI
>>> df = logging.Formatter('$asctime $name ${levelname}
...                        style='$')
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG me
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITI
>>>
```

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another, E
>>>
```

Logging calls (`logger.debug()`, `logger.info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using **`str.format()`** or **`string.Template`** syntax,

because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and $- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwar
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as _ (double underscore — not to be confused with _, the single underscore used as a synonym/alias for **`gettext.gettext()`** or its brethren).

The above classes are not included in Python, though they’re easy

enough to copy and paste into your own code. They can be used as follows (assuming that they're declared in a module called `wherever`):

```
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2, name='placeho
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f},
...       point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='pla
Message with 2 placeholders
>>>
```

While the above examples use `print()` to show how the formatting works, you would of course use `logger.debug()` or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the _ notation is just syntax sugar for a constructor call to one of the XXXMessage classes.

If you prefer, you can use a **`LoggerAdapter`** to achieve a similar effect to the above, as in the following example:

```
import logging

class Message:
    def __init__(self, fmt, args):
```

```
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super().__init__(logger, extra or {})

    def log(self, level, msg, /, *args, **kwargs):
        if self.isEnabledFor(level):
            msg, kwargs = self.process(msg, kwargs)
            self.logger._log(level, Message(msg, args),

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}', 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()
```

The above script should log the message `Hello, world!` when run with Python 3.2 or later.

Customizing `LogRecord`

Every logging event is represented by a **`LogRecord`** instance. When an event is logged and not filtered out by a logger's level, a **`LogRecord`** is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two places where this creation was done:

- **`Logger.makeRecord()`**, which is called in the normal process of logging an event. This invoked **`LogRecord`**

directly to create an instance.
- **makeLogRecord()**, which is called with a dictionary containing attributes to be added to the LogRecord. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a **SocketHandler**, or in JSON form via an **HTTPHandler**).

This has usually meant that if you need to do anything special with a **LogRecord**, you've had to do one of the following.

- Create your own **Logger** subclass, which overrides **Logger.makeRecord()**, and set it using **setLoggerClass()** before any loggers that you care about are instantiated.
- Add a **Filter** to a logger or handler, which does the necessary special manipulation you need when its **filter()** method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own **Logger** subclass, and the one which did this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of **LogRecord**. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a **NullHandler** attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger — so output from that handler would not reflect the intentions of the library developer.

In Python 3.2 and later, **LogRecord** creation is done through a factory, which you can specify. The factory is just a callable you can

set with **setLogRecordFactory()**, and interrogate with **getLogRecordFactory()**. The factory is invoked with the same signature as the **LogRecord** constructor, as **LogRecord** is the default setting for the factory.

This approach allows a custom factory to control all aspects of LogRecord creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdecafbad
    return record

logging.setLogRecordFactory(record_factory)
```

This pattern allows different libraries to chain factories together, and as long as they don't overwrite each other's attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a **Filter** does not provide the desired result.

Subclassing QueueHandler - a ZeroMQ example

You can use a **QueueHandler** subclass to send messages to other kinds of queues, for example a ZeroMQ 'publish' socket. In the example below,the socket is created separately and passed to the handler (as its 'queue'):

```
import zmq   # using pyzmq, the Python binding for ZeroM
import json  # for serializing records portably

ctx = zmq.Context()
```

```
sock = zmq.Socket(ctx, zmq.PUB)  # or zmq.PUSH, or other
sock.bind('tcp://*:5556')        # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```
class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        super().__init__(socket)

    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

    def close(self):
        self.queue.close()
```

Subclassing QueueListener - a ZeroMQ example

You can also subclass **`QueueListener`** to get messages from other kinds of queues, for example a ZeroMQ 'subscribe' socket. Here's an example:

```
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, /, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt_string(zmq.SUBSCRIBE, '')  # s
```

```
        socket.connect(uri)
        super().__init__(socket, *handlers, **kwargs)

    def dequeue(self):
        msg = self.queue.recv_json()
        return logging.makeLogRecord(msg)
```

A basic logging tutorial

A more advanced logging tutorial

An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the documentation on the Django project [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging]. This dictionary is passed to `dictConfig()` to put the configuration into effect:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'verbose': {
            'format': '%(levelname)s %(asctime)s %(modul
        },
```

```
        'simple': {
            'format': '%(levelname)s %(message)s'
        },
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        }
    },
    'handlers': {
        'null': {
            'level':'DEBUG',
            'class':'django.utils.log.NullHandler',
        },
        'console':{
            'level':'DEBUG',
            'class':'logging.StreamHandler',
            'formatter': 'simple'
        },
        'mail_admins': {
            'level': 'ERROR',
            'class': 'django.utils.log.AdminEmailHandler
            'filters': ['special']
        }
    },
    'loggers': {
        'django': {
            'handlers':['null'],
            'propagate': True,
            'level':'INFO',
        },
        'django.request': {
            'handlers': ['mail_admins'],
            'level': 'ERROR',
            'propagate': False,
        },
        'myproject.custom': {
```

```
            'handlers': ['console', 'mail_admins'],
            'level': 'INFO',
            'filters': ['special']
        }
    }
}
```

For more information about this configuration, you can see the relevant section [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging] of the Django documentation.

Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following snippet, which shows zlib-based compression of the log file:

```
def namer(name):
    return name + ".gz"

def rotator(source, dest):
    with open(source, "rb") as sf:
        data = sf.read()
        compressed = zlib.compress(data, 9)
        with open(dest, "wb") as df:
            df.write(compressed)
    os.remove(source)

rh = logging.handlers.RotatingFileHandler(...)
rh.rotator = rotator
rh.namer = namer
```

These are not “true” .gz files, as they are bare compressed data, with no “container” such as you’d find in an actual gzip file. This snippet is just for illustration purposes.

A more elaborate multiprocessing

example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here's the script - the docstrings and the comments hopefully explain how it works:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, curre
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in the
    dispatches events to loggers based on the name in th
    which then get dispatched, by the logging system, to
    configured for those loggers.
    """

    def handle(self, record):
        if record.name == "root":
```

```
            logger = logging.getLogger()
        else:
            logger = logging.getLogger(record.name)

        if logger.isEnabledFor(record.levelno):
            # The process name is transformed just to sh
            # doing the logging to files and console

Inserting a BOM into messages sent to a

SysLogHandler

RFC 5424 [https://datatracker.ietf.org/doc/html/rfc5424.html] requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the **relevant section of the specification** [https://datatracker.ietf.org/doc/html/rfc5424.html#section-6].)

In Python 3.1, code was added to **`SysLogHandler`** to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a **`Formatter`** instance to your **`SysLogHandler`** instance, with a format string such as:

   ```
   'ASCII section\ufeffUnicode section'
   ```

   The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution is always ASCII (that way, it will remain unchanged after UTF-8 encoding).

3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that's fine – it will be encoded using UTF-8.

The formatted message *will* be encoded using UTF-8 encoding by `SysLogHandler`. If you follow the above rules, you should be able to produce **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages. If you don't, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.

Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which *is* capable of being parsed by a program (without needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```
import json
import logging

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message, json.dumps(s

_ = StructuredMessage   # optional, to improve readabili

logging.basicConfig(level=logging.INFO, format='%(messag
logging.info(_('message 1', foo='bar', bar='baz', num=12
```

If the above script is run, it prints:

```
message 1 >>> {"fnum": 123.456, "num": 123, "bar": "baz"
```

Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```
import json
import logging

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
        elif isinstance(o, str):
            return o.encode('unicode_escape').decode('as
        return super().default(o)

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwargs)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage   # optional, to improve readabili

def main():
    logging.basicConfig(level=logging.INFO, format='%(me
    logging.info(_('message 1', set_value={1, 2, 3}, sno

if __name__ == '__main__':
    main()
```

When the above script is run, it prints:

```
message 1 >>> {"snowman": "\u2603", "set_value": [1, 2,
```

Note that the order of items might be different according to the version of Python used.

Customizing handlers with `dictConfig()`

There are times when you want to customize logging handlers in particular ways, and if you use `dictConfig()` you may be able to do this without subclassing. As an example, consider that you may want to set the ownership of a log file. On POSIX, this is easily done using `shutil.chown()`, but the file handlers in the stdlib don't offer built-in support. You can customize handler creation using a plain function such as:

```
def owned_file_handler(filename, mode='a', encoding=None
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)
```

You can then specify, in a logging configuration passed to `dictConfig()`, that a logging handler be created by calling this function:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)
        },
    },
    'handlers': {
        'file':{
            # The values below are popped from this dict
            # used to create the handler, set the handle
            # its formatter.
            '()': owned_file_handler,
```

```
            'level':'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}
```

In this example I am setting the ownership using the `pulse` user and group, just for the purposes of illustration. Putting it together into a working script, `chowntest.py`:

```
import logging, logging.config, os, shutil

def owned_file_handler(filename, mode='a', encoding=None
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)
        },
    },
    'handlers': {
        'file':{
```

```
            # The values below are popped from this dict
            # used to create the handler, set the handle
            # its formatter.
            '()': owned_file_handler,
            'level':'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}

logging.config.dictConfig(LOGGING)
logger = logging.getLogger('mylogger')
logger.debug('A debug message')
```

To run this, you will probably need to run as `root`:

```
$ sudo python3.3 chowntest.py
$ cat chowntest.log
2013-11-05 09:34:51,128 DEBUG mylogger A debug message
$ ls -l chowntest.log
-rw-r--r-- 1 pulse pulse 55 2013-11-05 09:34 chowntest.l
```

Note that this example uses Python 3.3 because that's where **`shutil.chown()`** makes an appearance. This approach should work with any Python version that supports **`dictConfig()`** - namely, Python 2.7, 3.2 or later. With pre-3.3 versions, you would need to implement the actual ownership change using e.g. **`os.chown()`**.

In practice, the handler-creating function may be in a utility module somewhere in your project. Instead of the line in the configuration:

```
'()': owned_file_handler,
```

you could use e.g.:

```
'()': 'ext://project.util.owned_file_handler',
```

where `project.util` can be replaced with the actual name of the package where the function resides. In the above working script, using `'ext://__main__.owned_file_handler'` should work. Here, the actual callable is resolved by **`dictConfig()`** from the `ext://` specification.

This example hopefully also points the way to how you could implement other types of file change - e.g. setting specific POSIX permission bits - in the same way, using **`os.chmod()`**.

Of course, the approach could also be extended to types of handler other than a **`FileHandler`** - for example, one of the rotating file handlers, or a different type of handler altogether.

Using particular formatting styles throughout your application

In Python 3.2, the **`Formatter`** gained a `style` keyword parameter which, while defaulting to `%` for backward compatibility, allowed the specification of `{` or `$` to support the formatting approaches supported by **`str.format()`** and **`string.Template`**. Note that this governs the formatting of logging messages for final output to logs, and is completely orthogonal to how an individual logging message is constructed.

Logging calls (**`debug()`**, **`info()`** etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to

be added to the log). So you cannot directly make logging calls using **`str.format()`** or **`string.Template`** syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There have been suggestions to associate format styles with specific loggers, but that approach also runs into backward compatibility problems because any existing code could be using a given logger name and using %-formatting.

For logging to work interoperably between any third-party libraries and your code, decisions about formatting need to be made at the level of the individual logging call. This opens up a couple of ways in which alternative formatting styles can be accommodated.

Using LogRecord factories

In Python 3.2, along with the **`Formatter`** changes mentioned above, the logging package gained the ability to allow users to set their own **`LogRecord`** subclasses, using the **`setLogRecordFactory()`** function. You can use this to set your own subclass of **`LogRecord`**, which does the Right Thing by overriding the **`getMessage()`** method. The base class implementation of this method is where the `msg % args` formatting happens, and where you can substitute your alternate formatting; however, you should be careful to support all formatting styles and allow %-formatting as the default, to ensure interoperability with other code. Care should also be taken to call `str(self.msg)`, just as the base implementation does.

Refer to the reference documentation on **`setLogRecordFactory()`** and **`LogRecord`** for more information.

Using custom message objects

There is another, perhaps simpler way that you can use {}- and $-formatting to construct your individual log messages. You may

recall (from Using arbitrary objects as messages) that when logging you can use an arbitrary object as a message format string, and that the logging package will call **`str()`** on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwar
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. If you find it a little unwieldy to use the class names whenever you want to log something, you can make it more palatable if you use an alias such as `M` or `_` for the message (or perhaps `__`, if you are using `_` for localization).

Examples of this approach are given below. Firstly, formatting with **`str.format()`**:

```
>>> __ = BraceMessage
>>> print(__('Message with {0} {1}', 2, 'placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
```

```
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f},
Message with coordinates: (0.50, 0.50)
```

Secondly, formatting with **`string.Template`**:

```
>>> __ = DollarMessage
>>> print(__('Message with $num $what', num=2, what='pla
Message with 2 placeholders
>>>
```

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the _ notation is just syntax sugar for a constructor call to one of the `XXXMessage` classes shown above.

Configuring filters with **`dictConfig()`**

You *can* configure filters using **`dictConfig()`**, though it might not be obvious at first glance how to do it (hence this recipe). Since **`Filter`** is the only filter class included in the standard library, and it is unlikely to cater to many requirements (it's only there as a base class), you will typically need to define your own **`Filter`** subclass with an overridden **`filter()`** method. To do this, specify the `()` key in the configuration dictionary for the filter, specifying a callable which will be used to create the filter (a class is the most obvious, but you can provide any callable which returns a **`Filter`** instance). Here is a complete example:

```
import logging
import logging.config
import sys

class MyFilter(logging.Filter):
```

```
    def __init__(self, param=None):
        self.param = param

    def filter(self, record):
        if self.param is None:
            allow = True
        else:
            allow = self.param not in record.msg
        if allow:
            record.msg = 'changed: ' + record.msg
        return allow

LOGGING = {
    'version': 1,
    'filters': {
        'myfilter': {
            '()': MyFilter,
            'param': 'noshow',
        }
    },
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
            'filters': ['myfilter']
        }
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['console']
    },
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.debug('hello')
    logging.debug('hello - noshow')
```

This example shows how you can pass configuration data to the callable which constructs the instance, in the form of keyword

parameters. When run, the above script will print:

```
changed: hello
```

which shows that the filter is working as configured.

A couple of extra points to note:

- If you can't refer to the callable directly in the configuration (e.g. if it lives in a different module, and you can't import it directly where the configuration dictionary is), you can use the form `ext://...` as described in Access to external objects. For example, you could have used the text `'ext://__main__.MyFilter'` instead of `MyFilter` in the above example.
- As well as for filters, this technique can also be used to configure custom handlers and formatters. See User-defined objects for more information on how logging supports using user-defined objects in its configuration, and see the other cookbook recipe Customizing handlers with dictConfig() above.

Customized exception formatting

There might be times when you want to do customized exception formatting - for argument's sake, let's say you want exactly one line per logged event, even when exception information is present. You can do this with a custom formatter class, as shown in the following example:

```
import logging

class OneLineExceptionFormatter(logging.Formatter):
    def formatException(self, exc_info):
        """
        Format an exception so that it prints on a singl
        """
        result = super().formatException(exc_info)
        return repr(result)  # or format into one line h
```

```
    def format(self, record):
        s = super().format(record)
        if record.exc_text:
            s = s.replace('\n', '') + '|'
        return s

def configure_logging():
    fh = logging.FileHandler('output.txt', 'w')
    f = OneLineExceptionFormatter('%(asctime)s|%(levelna
                                  '%d/%m/%Y %H:%M:%S')
    fh.setFormatter(f)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(fh)

def main():
    configure_logging()
    logging.info('Sample message')
    try:
        x = 1 / 0
    except ZeroDivisionError as e:
        logging.exception('ZeroDivisionError: %s', e)

if __name__ == '__main__':
    main()
```

When run, this produces a file with exactly two lines:

```
28/01/2015 07:21:23|INFO|Sample message|
28/01/2015 07:21:23|ERROR|ZeroDivisionError: integer div
```

While the above treatment is simplistic, it points the way to how exception information can be formatted to your liking. The **`traceback`** module may be helpful for more specialized needs.

Speaking logging messages

There might be situations when it is desirable to have logging messages rendered in an audible rather than a visible format. This is

easy to do if you have text-to-speech (TTS) functionality available in your system, even if it doesn't have a Python binding. Most TTS systems have a command line program you can run, and this can be invoked from a handler using **subprocess**. It's assumed here that TTS command line programs won't expect to interact with users or take a long time to complete, and that the frequency of logged messages will be not so high as to swamp the user with messages, and that it's acceptable to have the messages spoken one at a time rather than concurrently, The example implementation below waits for one message to be spoken before the next is processed, and this might cause other handlers to be kept waiting. Here is a short example showing the approach, which assumes that the `espeak` TTS package is available:

```
import logging
import subprocess
import sys

class TTSHandler(logging.Handler):
    def emit(self, record):
        msg = self.format(record)
        # Speak slowly in a female English voice
        cmd = ['espeak', '-s150', '-ven+f3', msg]
        p = subprocess.Popen(cmd, stdout=subprocess.PIPE
                             stderr=subprocess.STDOUT)
        # wait for the program to finish
        p.communicate()

def configure_logging():
    h = TTSHandler()
    root = logging.getLogger()
    root.addHandler(h)
    # the default formatter just returns the message
    root.setLevel(logging.DEBUG)

def main():
    logging.info('Hello')
    logging.debug('Goodbye')
```

```
if __name__ == '__main__':
    configure_logging()
    sys.exit(main())
```

When run, this script should say “Hello” and then “Goodbye” in a female voice.

The above approach can, of course, be adapted to other TTS systems and even other systems altogether which can process messages via external programs run from a command line.

Buffering logging messages and outputting them conditionally

There might be situations where you want to log messages in a temporary area and only output them if a certain condition occurs. For example, you may want to start logging debug events in a function, and if the function completes without errors, you don’t want to clutter the log with the collected debug information, but if there is an error, you want all the debug information to be output as well as the error.

Here is an example which shows how you could do this using a decorator for your functions where you want logging to behave this way. It makes use of the `logging.handlers.MemoryHandler`, which allows buffering of logged events until some condition occurs, at which point the buffered events are `flushed` - passed to another handler (the `target` handler) for processing. By default, the `MemoryHandler` flushed when its buffer gets filled up or an event whose level is greater than or equal to a specified threshold is seen. You can use this recipe with a more specialised subclass of `MemoryHandler` if you want custom flushing behavior.

The example script has a simple function, `foo`, which just cycles through all the logging levels, writing to `sys.stderr` to say what level it’s about to log at, and then actually logging a message at that level. You can pass a parameter to `foo` which, if true, will log at ERROR and CRITICAL levels - otherwise, it only logs at DEBUG, INFO and WARNING levels.

The script just arranges to decorate `foo` with a decorator which will do the conditional logging that's required. The decorator takes a logger as a parameter and attaches a memory handler for the duration of the call to the decorated function. The decorator can be additionally parameterised using a target handler, a level at which flushing should occur, and a capacity for the buffer (number of records buffered). These default to a **`StreamHandler`** which writes to `sys.stderr`, `logging.ERROR` and `100` respectively.

Here's the script:

```
import logging
from logging.handlers import MemoryHandler
import sys

logger = logging.getLogger(__name__)
logger.addHandler(logging.NullHandler())

def log_if_errors(logger, target_handler=None, flush_lev
    if target_handler is None:
        target_handler = logging.StreamHandler()
    if flush_level is None:
        flush_level = logging.ERROR
    if capacity is None:
        capacity = 100
    handler = MemoryHandler(capacity, flushLevel=flush_l

    def decorator(fn):
        def wrapper(*args, **kwargs):
            logger.addHandler(handler)
            try:
                return fn(*args, **kwargs)
            except Exception:
                logger.exception('call failed')
                raise
            finally:
                super(MemoryHandler, handler).flush()
                logger.removeHandler(handler)
        return wrapper
```

```
    return decorator

def write_line(s):
    sys.stderr.write('%s\n' % s)

def foo(fail=False):
    write_line('about to log at DEBUG ...')
    logger.debug('Actually logged at DEBUG')
    write_line('about to log at INFO ...')
    logger.info('Actually logged at INFO')
    write_line('about to log at WARNING ...')
    logger.warning('Actually logged at WARNING')
    if fail:
        write_line('about to log at ERROR ...')
        logger.error('Actually logged at ERROR')
        write_line('about to log at CRITICAL ...')
        logger.critical('Actually logged at CRITICAL')
    return fail

decorated_foo = log_if_errors(logger)(foo)

if __name__ == '__main__':
    logger.setLevel(logging.DEBUG)
    write_line('Calling undecorated foo with False')
    assert not foo(False)
    write_line('Calling undecorated foo with True')
    assert foo(True)
    write_line('Calling decorated foo with False')
    assert not decorated_foo(False)
    write_line('Calling decorated foo with True')
    assert decorated_foo(True)
```

When this script is run, the following output should be observed:

```
Calling undecorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
```

```
Calling undecorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
about to log at ERROR ...
about to log at CRITICAL ...
Calling decorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
Calling decorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
about to log at ERROR ...
Actually logged at DEBUG
Actually logged at INFO
Actually logged at WARNING
Actually logged at ERROR
about to log at CRITICAL ...
Actually logged at CRITICAL
```

As you can see, actual logging output only occurs when an event is logged whose severity is ERROR or greater, but in that case, any previous events at lower severities are also logged.

You can of course use the conventional means of decoration:

```
@log_if_errors(logger)
def foo(fail=False):
    ...
```

Sending logging messages to email, with buffering

To illustrate how you can send log messages via email, so that a set number of messages are sent per email, you can subclass **`BufferingHandler`**. In the following example, which you can

adapt to suit your specific needs, a simple test harness is provided which allows you to run the script with command line arguments specifying what you typically need to send things via SMTP. (Run the downloaded script with the `-h` argument to see the required and optional arguments.)

```
import logging
import logging.handlers
import smtplib

class BufferingSMTPHandler(logging.handlers.BufferingHan
    def __init__(self, mailhost, port, username, passwor
                 subject, capacity):
        logging.handlers.BufferingHandler.__init__(self,
        self.mailhost = mailhost
        self.mailport = port
        self.username = username
        self.password = password
        self.fromaddr = fromaddr
        if isinstance(toaddrs, str):
            toaddrs = [toaddrs]
        self.toaddrs = toaddrs
        self.subject = subject
        self.setFormatter(logging.Formatter("%(asctime)s

    def flush(self):
        if len(self.buffer) > 0:
            try:
                smtp = smtplib.SMTP(self.mailhost, self.
                smtp.starttls()
                smtp.login(self.username, self.password)
                msg = "From: %s\r\nTo: %s\r\nSubject: %s
                for record in self.buffer:
                    s = self.format(record)
                    msg = msg + s + "\r\n"
                smtp.sendmail(self.fromaddr, self.toaddr
                smtp.quit()
            except Exception:
                if logging.raiseExceptions:
```

```
                    raise
            self.buffer = []

if __name__ == '__main__':
    import argparse

    ap = argparse.ArgumentParser()
    aa = ap.add_argument
    aa('host', metavar='HOST', help='SMTP server')
    aa('--port', '-p', type=int, default=587, help='SMTP
    aa('user', metavar='USER', help='SMTP username')
    aa('password', metavar='PASSWORD', help='SMTP passwo
    aa('to', metavar='TO', help='Addressee for emails')
    aa('sender', metavar='SENDER', help='Sender email ad
    aa('--subject', '-s',
       default='Test Logging email from Python logging m
       help='Subject of email')
    options = ap.parse_args()
    logger = logging.getLogger()
    logger.setLevel(logging.DEBUG)
    h = BufferingSMTPHandler(options.host, options.port,
                             options.password, options.s
                             options.to, options.subject
    logger.addHandler(h)
    for i in range(102):
        logger.info("Info index = %d", i)
    h.flush()
    h.close()
```

If you run this script and your SMTP server is correctly set up, you should find that it sends eleven emails to the addressee you specify. The first ten emails will each have ten log messages, and the eleventh will have two messages. That makes up 102 messages as specified in the script.

Formatting times using UTC (GMT) via configuration

Sometimes you want to format times using UTC, which can be done using a class such as `UTCFormatter`, shown below:

```
import logging
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime
```

and you can then use the `UTCFormatter` in your code instead of **`Formatter`**. If you want to do that via configuration, you can use the **`dictConfig()`** API with an approach illustrated by the following complete example:

```
import logging
import logging.config
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'utc': {
            '()': UTCFormatter,
            'format': '%(asctime)s %(message)s',
        },
        'local': {
            'format': '%(asctime)s %(message)s',
        }
    },
    'handlers': {
        'console1': {
            'class': 'logging.StreamHandler',
            'formatter': 'utc',
        },
        'console2': {
```

```
            'class': 'logging.StreamHandler',
            'formatter': 'local',
        },
    },
    'root': {
        'handlers': ['console1', 'console2'],
   }
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.warning('The local time is %s', time.asctime
```

When this script is run, it should print something like:

```
2015-10-17 12:53:29,501 The local time is Sat Oct 17 13:
2015-10-17 13:53:29,501 The local time is Sat Oct 17 13:
```

showing how the time is formatted both as local time and UTC, one for each handler.

Using a context manager for selective logging

There are times when it would be useful to temporarily change the logging configuration and revert it back after doing something. For this, a context manager is the most obvious way of saving and restoring the logging context. Here is a simple example of such a context manager, which allows you to optionally change the logging level and add a logging handler purely in the scope of the context manager:

```
import logging
import sys

class LoggingContext:
    def __init__(self, logger, level=None, handler=None,
        self.logger = logger
        self.level = level
```

```
        self.handler = handler
        self.close = close

    def __enter__(self):
        if self.level is not None:
            self.old_level = self.logger.level
            self.logger.setLevel(self.level)
        if self.handler:
            self.logger.addHandler(self.handler)

    def __exit__(self, et, ev, tb):
        if self.level is not None:
            self.logger.setLevel(self.old_level)
        if self.handler:
            self.logger.removeHandler(self.handler)
        if self.handler and self.close:
            self.handler.close()
        # implicit return of None => don't swallow excep
```

If you specify a level value, the logger's level is set to that value in the scope of the with block covered by the context manager. If you specify a handler, it is added to the logger on entry to the block and removed on exit from the block. You can also ask the manager to close the handler for you on block exit - you could do this if you don't need the handler any more.

To illustrate how it works, we can add the following block of code to the above:

```
if __name__ == '__main__':
    logger = logging.getLogger('foo')
    logger.addHandler(logging.StreamHandler())
    logger.setLevel(logging.INFO)
    logger.info('1. This should appear just once on stde
    logger.debug('2. This should not appear.')
    with LoggingContext(logger, level=logging.DEBUG):
        logger.debug('3. This should appear once on stde
    logger.debug('4. This should not appear.')
    h = logging.StreamHandler(sys.stdout)
```

```
    with LoggingContext(logger, level=logging.DEBUG, har
        logger.debug('5. This should appear twice - once
    logger.info('6. This should appear just once on stde
    logger.debug('7. This should not appear.')
```

We initially set the logger's level to `INFO`, so message #1 appears and message #2 doesn't. We then change the level to `DEBUG` temporarily in the following `with` block, and so message #3 appears. After the block exits, the logger's level is restored to `INFO` and so message #4 doesn't appear. In the next `with` block, we set the level to `DEBUG` again but also add a handler writing to `sys.stdout`. Thus, message #5 appears twice on the console (once via `stderr` and once via `stdout`). After the `with` statement's completion, the status is as it was before so message #6 appears (like message #1) whereas message #7 doesn't (just like message #2).

If we run the resulting script, the result is as follows:

```
$ python logctx.py
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once or
5. This should appear twice - once on stderr and once or
6. This should appear just once on stderr.
```

If we run it again, but pipe `stderr` to `/dev/null`, we see the following, which is the only message written to `stdout`:

```
$ python logctx.py 2>/dev/null
5. This should appear twice - once on stderr and once or
```

Once again, but piping `stdout` to `/dev/null`, we get:

```
$ python logctx.py >/dev/null
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once or
6. This should appear just once on stderr.
```

In this case, the message #5 printed to `stdout` doesn't appear, as

expected.

Of course, the approach described here can be generalised, for example to attach logging filters temporarily. Note that the above code works in Python 2 as well as Python 3.

A CLI application starter template

Here's an example which shows how you can:

- Use a logging level based on command-line arguments
- Dispatch to multiple subcommands in separate files, all logging at the same level in a consistent way
- Make use of simple, minimal configuration

Suppose we have a command-line application whose job is to stop, start or restart some services. This could be organised for the purposes of illustration as a file `app.py` that is the main script for the application, with individual commands implemented in `start.py`, `stop.py` and `restart.py`. Suppose further that we want to control the verbosity of the application via a command-line argument, defaulting to `logging.INFO`. Here's one way that `app.py` could be written:

```
import argparse
import importlib
import logging
import os
import sys

def main(args=None):
    scriptname = os.path.basename(__file__)
    parser = argparse.ArgumentParser(scriptname)
    levels = ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRI
    parser.add_argument('--log-level', default='INFO', c
    subparsers = parser.add_subparsers(dest='command',
                                       help='Available c
    start_cmd = subparsers.add_parser('start', help='Sta
    start_cmd.add_argument('name', metavar='NAME',
```

```
                                help='Name of service to star
    stop_cmd = subparsers.add_parser('stop',
                                     help='Stop one or m
    stop_cmd.add_argument('names', metavar='NAME', nargs
                          help='Name of service to stop'
    restart_cmd = subparsers.add_parser('restart',
                                        help='Restart or
    restart_cmd.add_argument('names', metavar='NAME', na
                             help='Name of service to re
    options = parser.parse_args()
    # the code to dispatch commands could all be in this
    # of illustration only, we implement each command in
    try:
        mod = importlib.import_module(options.command)
        cmd = getattr(mod, 'command')
    except (ImportError, AttributeError):
        print('Unable to find the code for command \'%s\
        return 1
    # Could get fancy here and load configuration from f
    logging.basicConfig(level=options.log_level,
                        format='%(levelname)s %(name)s %
    cmd(options)

if __name__ == '__main__':
    sys.exit(main())
```

And the `start`, `stop` and `restart` commands can be implemented in separate modules, like so for starting:

```
# start.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    logger.debug('About to start %s', options.name)
    # actually do the command processing here ...
    logger.info('Started the \'%s\' service.', options.n
```

and thus for stopping:

```
# stop.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in
        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i +
    logger.debug('About to stop %s', services)
    # actually do the command processing here ...
    logger.info('Stopped the %s service%s.', services, p
```

and similarly for restarting:

```
# restart.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in
        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i +
    logger.debug('About to restart %s', services)
```

```
    # actually do the command processing here ...
    logger.info('Restarted the %s service%s.', services,
```

If we run this application with the default log level, we get output like this:

```
$ python app.py start foo
INFO start Started the 'foo' service.

$ python app.py stop foo bar
INFO stop Stopped the 'foo' and 'bar' services.

$ python app.py restart foo bar baz
INFO restart Restarted the 'foo', 'bar' and 'baz' servic
```

The first word is the logging level, and the second word is the module or package name of the place where the event was logged.

If we change the logging level, then we can change the information sent to the log. For example, if we want more information:

```
$ python app.py --log-level DEBUG start foo
DEBUG start About to start foo
INFO start Started the 'foo' service.

$ python app.py --log-level DEBUG stop foo bar
DEBUG stop About to stop 'foo' and 'bar'
INFO stop Stopped the 'foo' and 'bar' services.

$ python app.py --log-level DEBUG restart foo bar baz
DEBUG restart About to restart 'foo', 'bar' and 'baz'
INFO restart Restarted the 'foo', 'bar' and 'baz' servic
```

And if we want less:

```
$ python app.py --log-level WARNING start foo
$ python app.py --log-level WARNING stop foo bar
$ python app.py --log-level WARNING restart foo bar baz
```

In this case, the commands don’t print anything to the console,

since nothing at `WARNING` level or above is logged by them.

A Qt GUI for logging

A question that comes up from time to time is about how to log to a GUI application. The Qt [https://www.qt.io/] framework is a popular cross-platform UI framework with Python bindings using PySide2 [https://pypi.org/project/PySide2/] or PyQt5 [https://pypi.org/project/PyQt5/] libraries.

The following example shows how to log to a Qt GUI. This introduces a simple `QtHandler` class which takes a callable, which should be a slot in the main thread that does GUI updates. A worker thread is also created to show how you can log to the GUI from both the UI itself (via a button for manual logging) as well as a worker thread doing work in the background (here, just logging messages at random levels with random short delays in between).

The worker thread is implemented using Qt's `QThread` class rather than the **`threading`** module, as there are circumstances where one has to use `QThread`, which offers better integration with other `Qt` components.

The code should work with recent releases of either `PySide2` or `PyQt5`. You should be able to adapt the approach to earlier versions of Qt. Please refer to the comments in the code snippet for more detailed information.

```
import datetime
import logging
import random
import sys
import time

# Deal with minor differences between PySide2 and PyQt5
try:
    from PySide2 import QtCore, QtGui, QtWidgets
    Signal = QtCore.Signal
    Slot = QtCore.Slot
except ImportError:
```

```
    from PyQt5 import QtCore, QtGui, QtWidgets
    Signal = QtCore.pyqtSignal
    Slot = QtCore.pyqtSlot

logger = logging.getLogger(__name__)

#
# Signals need to be contained in a QObject or subclass
# initialized.
#
class Signaller(QtCore.QObject):
    signal = Signal(str, logging.LogRecord)

#
# Output to a Qt GUI is only supposed to happen on the m
# handler is designed to take a slot function which is s
# thread. In this example, the function takes a string a
# formatted log message, and the log record which genera
# string is just a convenience - you could format a stri
# you like in the slot function itself.
#
# You specify the slot function to do whatever GUI updat
# doesn't know or care about specific UI elements.
#
class QtHandler(logging.Handler):

Logging to syslog with RFC5424 support

Although **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html] dates from 2009, most syslog servers are configured by detault to use the older **RFC 3164** [https://datatracker.ietf.org/doc/html/rfc3164.html], which hails from 2001. When `logging` was added to Python in 2003, it supported the earlier (and only existing) protocol at the time. Since RFC5424 came out, as there has not been widespread deployment of it in syslog servers, the **`SysLogHandler`** functionality has not been updated.

RFC 5424 contains some useful features such as support for structured data, and if you need to be able to log to a syslog server with support for it, you can do so with a subclassed handler which looks something like this:

```
import datetime
import logging.handlers
import re
import socket
import time

class SysLogHandler5424(logging.handlers.SysLogHandler):

    tz_offset = re.compile(r'([+-]\d{2})(\d{2})$')
    escaped = re.compile(r'([\]"\\])')

    def __init__(self, *args, **kwargs):
        self.msgid = kwargs.pop('msgid', None)
        self.appname = kwargs.pop('appname', None)
        super().__init__(*args, **kwargs)

    def format(self, record):
        version = 1
```

```
asctime = datetime.datetime.fromtimestamp(record
m = self.tz_offset.match(time.strftime('%z'))
has_offset = False
if m and time.timezone:
    hrs, mins = m.groups()
    if int(hrs) or int(mins):
        has_offset = True
if not has_offset:
    asctime += 'Z'
else:
    asctime += f'{hrs}:{mins}'
try:
    hostname = socket.gethostname()
except Exception:
    hostname = '-'
appname = self.appname or '-'
procid = record.process
msgid = '-'
msg = super().format(record)
sdata = '-'
if hasattr(record, 'structured_data'):
    sd = record.structured_data
    # This should be a dict where the keys are S
    # dict mapping PARAM-NAME to PARAM-VALUE (re
    # mean)
    # There's no error checking here - it's pure
    # can adapt this code for use in production
    parts = []

    def replacer(m):
        g = m.groups()
        return '\\' + g[0]

    for sdid, dv in sd.items():
        part = f'[{sdid}'
        for k, v in dv.items():
            s = str(v)
            s = self.escaped.sub(replacer, s)
```

```
                    part += f' {k}="{s}"'
                part += ']'
                parts.append(part)
            sdata = ''.join(parts)
        return f'{version} {asctime} {hostname} {appname
```

You'll need to be familiar with RFC 5424 to fully understand the above code, and it may be that you have slightly different needs (e.g. for how you pass structural data to the log). Nevertheless, the above should be adaptable to your speciric needs. With the above handler, you'd pass structured data using something like this:

```
sd = {
    'foo@12345': {'bar': 'baz', 'baz': 'bozz', 'fizz': r
    'foo@54321': {'rab': 'baz', 'zab': 'bozz', 'zzif': r
}
extra = {'structured_data': sd}
i = 1
logger.debug('Message %d', i, extra=extra)
```

How to treat a logger like an output stream

Sometimes, you need to interface to a third-party API which expects a file-like object to write to, but you want to direct the API's output to a logger. You can do this using a class which wraps a logger with a file-like API. Here's a short script illustrating such a class:

```
import logging

class LoggerWriter:
    def __init__(self, logger, level):
        self.logger = logger
        self.level = level

    def write(self, message):
        if message != '\n':  # avoid printing bare newli
            self.logger.log(self.level, message)
```

```
    def flush(self):
        # doesn't actually do anything, but might be exp
        # object - so optional depending on your situati
        pass

    def close(self):
        # doesn't actually do anything, but might be exp
        # object - so optional depending on your situati
        # to set a flag so that later calls to write rai
        pass

def main():
    logging.basicConfig(level=logging.DEBUG)
    logger = logging.getLogger('demo')
    info_fp = LoggerWriter(logger, logging.INFO)
    debug_fp = LoggerWriter(logger, logging.DEBUG)
    print('An INFO message', file=info_fp)
    print('A DEBUG message', file=debug_fp)

if __name__ == "__main__":
    main()
```

When this script is run, it prints

```
INFO:demo:An INFO message
DEBUG:demo:A DEBUG message
```

You could also use `LoggerWriter` to redirect `sys.stdout` and `sys.stderr` by doing something like this:

```
import sys

sys.stdout = LoggerWriter(logger, logging.INFO)
sys.stderr = LoggerWriter(logger, logging.WARNING)
```

You should do this *after* configuring logging for your needs. In the above example, the **`basicConfig()`** call does this (using the `sys.stderr` value *before* it is overwritten by a `LoggerWriter` instance). Then, you'd get this kind of result:

```
>>> print('Foo')
INFO:demo:Foo
>>> print('Bar', file=sys.stderr)
WARNING:demo:Bar
>>>
```

Of course, the examples above show output according to the format used by **`basicConfig()`**, but you can use a different formatter when you configure logging.

Note that with the above scheme, you are somewhat at the mercy of buffering and the sequence of write calls which you are intercepting. For example, with the definition of `LoggerWriter` above, if you have the snippet

```
sys.stderr = LoggerWriter(logger, logging.WARNING)
1 / 0
```

then running the script results in

```
WARNING:demo:Traceback (most recent call last):

WARNING:demo:  File "/home/runner/cookbook-loggerwriter/

WARNING:demo:
WARNING:demo:main()
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/

WARNING:demo:
WARNING:demo:1 / 0
WARNING:demo:ZeroDivisionError
WARNING:demo::
WARNING:demo:division by zero
```

As you can see, this output isn't ideal. That's because the underlying code which writes to `sys.stderr` makes mutiple writes, each of which results in a separate logged line (for example, the last three lines above). To get around this problem, you need to buffer things and only output log lines when newlines are seen. Let's use a slghtly better implementation of `LoggerWriter`:

```
class BufferingLoggerWriter(LoggerWriter):
    def __init__(self, logger, level):
        super().__init__(logger, level)
        self.buffer = ''

    def write(self, message):
        if '\n' not in message:
            self.buffer += message
        else:
            parts = message.split('\n')
            if self.buffer:
                s = self.buffer + parts.pop(0)
                self.logger.log(self.level, s)
            self.buffer = parts.pop()
            for part in parts:
                self.logger.log(self.level, part)
```

This just buffers up stuff until a newline is seen, and then logs complete lines. With this approach, you get better output:

```
WARNING:demo:Traceback (most recent call last):
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
WARNING:demo:    main()
WARNING:demo:  File "/home/runner/cookbook-loggerwriter/
WARNING:demo:    1/0
WARNING:demo:ZeroDivisionError: division by zero
```

Patterns to avoid

Although the preceding sections have described ways of doing things you might need to do or deal with, it is worth mentioning some usage patterns which are *unhelpful*, and which should therefore be avoided in most cases. The following sections are in no particular order.

Opening the same log file multiple times

On Windows, you will generally not be able to open the same file multiple times as this will lead to a “file is in use by another

process" error. However, on POSIX platforms you'll not get any errors if you open the same file multiple times. This could be done accidentally, for example by:

- Adding a file handler more than once which references the same file (e.g. by a copy/paste/forget-to-change error).
- Opening two files that look different, as they have different names, but are the same because one is a symbolic link to the other.
- Forking a process, following which both parent and child have a reference to the same file. This might be through use of the `multiprocessing` module, for example.

Opening a file multiple times might *appear* to work most of the time, but can lead to a number of problems in practice:

- Logging output can be garbled because multiple threads or processes try to write to the same file. Although logging guards against concurrent use of the same handler instance by multiple threads, there is no such protection if concurrent writes are attempted by two different threads using two different handler instances which happen to point to the same file.
- An attempt to delete a file (e.g. during file rotation) silently fails, because there is another reference pointing to it. This can lead to confusion and wasted debugging time - log entries end up in unexpected places, or are lost altogether. Or a file that was supposed to be moved remains in place, and grows in size unexpectedly despite size-based rotation being supposedly in place.

Use the techniques outlined in Logging to a single file from multiple processes to circumvent such issues.

Using loggers as attributes in a class or passing them as parameters

While there might be unusual cases where you'll need to do this, in general there is no point because loggers are singletons. Code can always access a given logger instance by name using

`logging.getLogger(name)`, so passing instances around and holding them as instance attributes is pointless. Note that in other languages such as Java and C#, loggers are often static class attributes. However, this pattern doesn't make sense in Python, where the module (and not the class) is the unit of software decomposition.

Adding handlers other than `NullHandler` to a logger in a library

Configuring logging by adding handlers, formatters and filters is the responsibility of the application developer, not the library developer. If you are maintaining a library, ensure that you don't add handlers to any of your loggers other than a **`NullHandler`** instance.

Creating a lot of loggers

Loggers are singletons that are never freed during a script execution, and so creating lots of loggers will use up memory which can't then be freed. Rather than create a logger per e.g. file processed or network connection made, use the existing mechanisms for passing contextual information into your logs and restrict the loggers created to those describing areas within your application (generally modules, but occasionally slightly more fine-grained than that).

Basic Tutorial

Advanced Tutorial

Regular Expression HOWTO

Author

A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.

Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular

expressions. There are also tasks that *can* be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.

Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { } [ ] \ | ( )
```

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of

characters can be indicated by giving two characters and separating them by a `'-'`. For example, `[abc]` will match any of the characters `a`, `b`, or `c`; this is the same as `[a-c]`, which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be `[a-z]`.

Metacharacters (except `\`) are not active inside classes. For example, `[akm$]` will match any of the characters `'a'`, `'k'`, `'m'`, or `'$'`; `'$'` is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by *complementing* the set. This is indicated by including a `'^'` as the first character of the class. For example, `[^5]` will match any character except `'5'`. If the caret appears elsewhere in a character class, it does not have special meaning. For example: `[5^]` will match either a `'5'` or a `'^'`.

Perhaps the most important metacharacter is the backslash, `\`. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a `[` or `\`, you can precede them with a backslash to remove their special meaning: `\[` or `\\`.

Some of the special sequences beginning with `'\'` represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace.

Let's take an example: `\w` matches any alphanumeric character. If the regex pattern is expressed in bytes, this is equivalent to the class `[a-zA-Z0-9_]`. If the regex pattern is a string, `\w` will match all the characters marked as letters in the Unicode database provided by the **`unicodedata`** module. You can use the more restricted definition of `\w` in a string pattern by supplying the **`re.ASCII`** flag when compiling the regular expression.

The following list of special sequences isn't complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of Regular Expression

Syntax in the Standard Library reference. In general, the Unicode versions match any character that's in the appropriate category in the Unicode database.

`\d`
: Matches any decimal digit; this is equivalent to the class `[0-9]`.

`\D`
: Matches any non-digit character; this is equivalent to the class `[^0-9]`.

`\s`
: Matches any whitespace character; this is equivalent to the class `[ \t\n\r\f\v]`.

`\S`
: Matches any non-whitespace character; this is equivalent to the class `[^ \t\n\r\f\v]`.

`\w`
: Matches any alphanumeric character; this is equivalent to the class `[a-zA-Z0-9_]`.

`\W`
: Matches any non-alphanumeric character; this is equivalent to the class `[^a-zA-Z0-9_]`.

These sequences can be included inside a character class. For example, `[\s,.]` is a character class that will match any whitespace character, or `','` or `'.'`.

The final metacharacter in this section is `.`. It matches anything except a newline character, and there's an alternate mode (**`re.DOTALL`**) where it will match even a newline. `.` is often used where you want to match "any character".

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn't already possible with the

methods available on strings. However, if that was the only additional capability of regexes, they wouldn't be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we'll look at is `*`. `*` doesn't match the literal character `'*'`; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, `ca*t` will match `'ct'` (0 `'a'` characters), `'cat'` (1 `'a'`), `'caaat'` (3 `'a'` characters), and so forth.

Repetitions such as `*` are *greedy*; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don't match, the matching engine will then back up and try again with fewer repetitions.

A step-by-step example will make this more obvious. Let's consider the expression `a[bcd]*b`. This matches the letter `'a'`, zero or more letters from the class `[bcd]`, and finally ends with a `'b'`. Now imagine matching this RE against the string `'abcbd'`.

Step	Matched	Explanation
1	`a`	The `a` in the RE matches.
2	`abcbd`	The engine matches `[bcd]*`, going as far as it can, which is to the end of the string.
3	*Failure*	Try `b`, but the current position is at the end of the string, so it fails.
4	`abcb`	Back up, so that `[bcd]*` matches one less character.
5	*Failure*	Try `b` again, but the current position is at the last character, which is a `'d'`.
6	`abc`	Back up again, so that `[bcd]*` is only matching `bc`.
7	`abcb`	Try `b` again. This time the character at the current position is `'b'`, so it succeeds.

The end of the RE has now been reached, and it has matched `'abcb'`. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for `[bcd]*`, and if that subsequently

fails, the engine will conclude that the string doesn't match the RE at all.

Another repeating metacharacter is `+`, which matches one or more times. Pay careful attention to the difference between `*` and `+`; `*` matches *zero* or more times, so whatever's being repeated may not be present at all, while `+` requires at least *one* occurrence. To use a similar example, `ca+t` will match `'cat'` (1 `'a'`), `'caaat'` (3 `'a'`s), but won't match `'ct'`.

There are two more repeating operators or quantifiers. The question mark character, `?`, matches either once or zero times; you can think of it as marking something as being optional. For example, `home-?brew` matches either `'homebrew'` or `'home-brew'`.

The most complicated quantifier is `{m,n}`, where *m* and *n* are decimal integers. This quantifier means there must be at least *m* repetitions, and at most *n*. For example, `a/{1,3}b` will match `'a/b'`, `'a//b'`, and `'a///b'`. It won't match `'ab'`, which has no slashes, or `'a////b'`, which has four.

You can omit either *m* or *n*; in that case, a reasonable value is assumed for the missing value. Omitting *m* is interpreted as a lower limit of 0, while omitting *n* results in an upper bound of infinity.

Readers of a reductionist bent may notice that the three other quantifiers can all be expressed using this notation. `{0,}` is the same as `*`, `{1,}` is equivalent to `+`, and `{0,1}` is the same as `?`. It's better to use `*`, `+`, or `?` when you can, simply because they're shorter and easier to read.

Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The **`re`** module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```
>>> import re
>>> p = re.compile('ab*')
>>> p
re.compile('ab*')
```

`re.compile()` also accepts an optional *flags* argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to **`re.compile()`** as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don't need REs at all, so there's no need to bloat the language specification by including them.) Instead, the **`re`** module is simply a C extension module included with Python, just like the **`socket`** or **`zlib`** modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

The Backslash Plague

As stated earlier, regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python's usage of the same character for the same purpose in string literals.

Let's say you want to write a RE that matches the string `\section`, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string `\\section`. The resulting string that must be passed to **`re.compile()`** must be `\\section`. However, to express this as

a Python string literal, both backslashes must be escaped *again*.

Characters	Stage
`tab`	Text string to be matched
`\\section`	Escaped backslash for `re.compile()`
`"\\\\section"`	Escaped backslashes for a string literal

In short, to match a literal backslash, one has to write `'\\\\'` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with `'r'`, so `r"\n"` is a two-character string containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

In addition, special escape sequences that are valid in regular expressions, but not valid as Python string literals, now result in a `DeprecationWarning` and will eventually become a `SyntaxError`, which means the sequences will be invalid if raw string notation or escaping the backslashes isn't used.

Regular String	Raw string
`"ab*"`	`r"ab*"`
`"\\\\section"`	`r"\\section"`
`"\\w+\\s+\\1"`	`r"\w+\s+\1"`

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the `re` docs for a complete listing.

Method/Attribute	Purpose
`match()`	Determine if the RE matches at the beginning of the string.

`search()`	Scan through a string, looking for any location where this RE matches.
`findall()`	Find all substrings where the RE matches, and returns them as a list.
`finditer()`	Find all substrings where the RE matches, and returns them as an iterator.

`match()` and **`search()`** return `None` if no match can be found. If they're successful, a match object instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the **`re`** module. If you have **`tkinter`** available, you may also want to look at Tools/demo/redemo.py [https://github.com/python/cpython/tree/3.11/Tools/demo/redemo.py], a demonstration program included with the Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. `redemo.py` can be quite useful when trying to debug a complicated RE.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the **`re`** module, and compile a RE:

```
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
re.compile('[a-z]+')
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means 'one or more repetitions'. **`match()`** should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of **`match()`** to make this clear.

```
>>> p.match("")
>>> print(p.match(""))
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, **`match()`** will return a match object, so you should store

the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> m
<re.Match object; span=(0, 5), match='tempo'>
```

Now you can query the match object for information about the matching string. Match object instances also have several methods and attributes; the most important ones are:

Method/Attribute	Purpose
group()	Return the string matched by the RE
start()	Return the starting position of the match
end()	Return the ending position of the match
span()	Return a tuple containing the (start, end) positions of the match

Trying these methods will soon clarify their meaning:

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

`group()` returns the substring that was matched by the RE. **`start()`** and **`end()`** return the starting and ending index of the match. **`span()`** returns both start and end indexes in a single tuple. Since the **`match()`** method only checks if the RE matches at the start of a string, **`start()`** will always be zero. However, the **`search()`** method of patterns scans through the string, so the match may not start at zero in that case.

```
>>> print(p.match('::: message'))
None
>>> m = p.search('::: message'); print(m)
<re.Match object; span=(4, 11), match='message'>
>>> m.group()
'message'
>>> m.span()
```

```
(4, 11)
```

In actual programs, the most common style is to store the match object in a variable, and then check if it was `None`. This usually looks like:

```
p = re.compile( ... )
m = p.match( 'string goes here' )
if m:
    print('Match found: ', m.group())
else:
    print('No match')
```

Two pattern methods return all of the matches for a pattern. **`findall()`** returns a list of matching strings:

```
>>> p = re.compile(r'\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 1
['12', '11', '10']
```

The `r` prefix, making the literal a raw string literal, is needed in this example because escape sequences in a normal “cooked” string literal that are not recognized by Python, as opposed to regular expressions, now result in a **`DeprecationWarning`** and will eventually become a **`SyntaxError`**. See The Backslash Plague.

`findall()` has to create the entire list before it can be returned as the result. The **`finditer()`** method returns a sequence of match object instances as an iterator:

```
>>> iterator = p.finditer('12 drummers drumming, 11 ...
>>> iterator
<callable_iterator object at 0x...>
>>> for match in iterator:
...     print(match.span())
...
(0, 2)
(22, 24)
(29, 31)
```

Module-Level Functions

You don't have to create a pattern object and call its methods; the **re** module also provides top-level functions called **match()**, **search()**, **findall()**, **sub()**, and so forth. These functions take the same arguments as the corresponding pattern method with the RE string added as the first argument, and still return either None or a match object instance.

```
>>> print(re.match(r'From\s+', 'Fromage amk'))
None
>>> re.match(r'From\s+', 'From amk Thu May 14 19:12:10 1
<re.Match object; span=(0, 5), match='From '>
```

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won't need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you're accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of loops, there's not much difference thanks to the internal cache.

Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the **re** module under two names, a long name such as **IGNORECASE** and a short, one-letter form such as **I**. (If you're familiar with Perl's pattern modifiers, the one-letter forms use the same letters; the short form of **re.VERBOSE** is **re.X**, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the **I** and **M** flags, for example.

Here's a table of the available flags, followed by a more detailed explanation of each one.

Flag	Meaning

ASCII, **A**
: Make several escapes like `\w`, `\b`, `\s` and `\d` match only on ASCII characters with the respective property.

DOTALL, **S**
: Make `.` match any character, including newlines.

IGNORECASE, **I**
: Do case-insensitive matches.

LOCALE, **L**
: Do a locale-aware match.

MULTILINE, **M**
: Multi-line matching, affecting `^` and `$`.

VERBOSE, **X** (for 'extended')
: Enable verbose REs (for REs that can be organized more cleanly and understandably.

I
IGNORECASE

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too. Full Unicode matching also works unless the **ASCII** flag is used to disable non-ASCII matches. When the Unicode patterns `[a-z]` or `[A-Z]` are used in combination with the **IGNORECASE** flag, they will match the 52 ASCII letters and 4 additional non-ASCII letters: 'İ' (U+0130, Latin capital letter I with dot above), 'ı' (U+0131, Latin small letter dotless i), 'ſ' (U+017F, Latin small letter long s) and 'K' (U+212A, Kelvin sign). `Spam` will match `'Spam'`, `'spam'`, `'spAM'`, or `'ſpam'` (the latter is matched only in Unicode mode). This lowercasing doesn't take the current locale into account; it will if you also set the **LOCALE** flag.

L
LOCALE

Make `\w`, `\W`, `\b`, `\B` and case-insensitive matching dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you're processing encoded French text, you'd want to be able to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]` in bytes patterns; it won't match bytes corresponding to `é` or `ç`. If your system is configured properly and a French locale is selected, certain C functions will tell the program that the byte corresponding to

é should also be considered a letter. Setting the **LOCALE** flag when compiling a regular expression will cause the resulting compiled object to use these C functions for `\w`; this is slower, but also enables `\w+` to match French words as you'd expect. The use of this flag is discouraged in Python 3 as the locale mechanism is very unreliable, it only handles one "culture" at a time, and it only works with 8-bit locales. Unicode matching is already enabled by default in Python 3 for Unicode (str) patterns, and it is able to handle different locales/languages.

M
MULTILINE

(`^` and `$` haven't been explained yet; they'll be introduced in section More Metacharacters.)

Usually `^` matches only at the beginning of the string, and `$` matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, `^` matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the `$` metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

S
DOTALL

Makes the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline.

A
ASCII

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

X

VERBOSE

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a `'#'` that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses **`re.VERBOSE`**; see how much easier it is to read?

```
charref = re.compile(r"""
 &[#]                # Start of a numeric entity re
 (
     0[0-7]+         # Octal form
   | [0-9]+          # Decimal form
   | x[0-9a-fA-F]+   # Hexadecimal form
 )
 ;                   # Trailing semicolon
""", re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```
charref = re.compile("&#(0[0-7]+"
                     "|[0-9]+"
                     "|x[0-9a-fA-F]+);")
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using **`re.VERBOSE`**.

More Pattern Power

So far we've only covered a part of the features of regular

expressions. In this section, we'll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven't covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are *zero-width assertions*. They don't cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, `\b` is an assertion that the current position is located at a word boundary; the position isn't changed by the `\b` at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

`|`

Alternation, or the "or" operator. If *A* and *B* are regular expressions, `A|B` will match any string that matches either *A* or *B*. `|` has very low precedence in order to make it work reasonably when you're alternating multi-character strings. `Crow|Servo` will match either `'Crow'` or `'Servo'`, not `'Cro'`, a `'w'` or an `'S'`, and `'ervo'`.

To match a literal `'|'`, use `\|`, or enclose it inside a character class, as in `[|]`.

`^`

Matches at the beginning of lines. Unless the **`MULTILINE`** flag has been set, this will only match at the beginning of the string. In **`MULTILINE`** mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word `From` only at the beginning of a line, the RE to use is `^From`.

```
>>> print(re.search('^From', 'From Here to Eternity
<re.Match object; span=(0, 4), match='From'>
```

```
>>> print(re.search('^From', 'Reciting From Memory'
None
```

To match a literal `'^'`, use `\^`.

`$`

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```
>>> print(re.search('}$', '{block}'))
<re.Match object; span=(6, 7), match='}'>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<re.Match object; span=(6, 7), match='}'>
```

To match a literal `'$'`, use `\$` or enclose it inside a character class, as in `[$]`.

`\A`

Matches only at the start of the string. When not in **`MULTILINE`** mode, `\A` and `^` are effectively the same. In **`MULTILINE`** mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

`\Z`

Matches only at the end of the string.

`\b`

Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<re.Match object; span=(3, 8), match='class'>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the `'r'` in front of the RE string.

```
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<re.Match object; span=(0, 7), match='\x08class\x08
```

Second, inside a character class, where there's no use for this assertion, `\b` represents the backspace character, for compatibility with Python's string literals.

`\B`

Another zero-width assertion, this is the opposite of `\b`, only matching when the current position is not at a word boundary.

Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a `':'`, like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header's value.

Groups are marked by the `'('`, `')'` metacharacters. `'('` and `')'` have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a quantifier, such as `*`, `+`, `?`, or `{m,n}`. For example, `(ab)*` will match zero or more repetitions of `ab`.

```
>>> p = re.compile('(ab)*')
>>> print(p.match('abababababab').span())
(0, 10)
```

Groups indicated with `'('`, `')'` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to **`group()`**, **`start()`**, **`end()`**, and **`span()`**. Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so match object methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture the span of text that they match.

```
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```
>>> p = re.compile('(a(b)c)d')
```

```
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

```
>>> m.group(2,1,2)
('b', 'abc', 'b')
```

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python's string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```
>>> p = re.compile(r'\b(\w+)\s+\1\b')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren't often useful for just searching through a string — there are few text formats which repeat data in this way — but you'll soon find out that they're *very* useful when performing string substitutions.

Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 is well known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with `\` without making Perl's regular expressions confusingly different from standard REs. If they chose `&` as a new metacharacter, for example, old expressions would be assuming that `&` was a regular character and wouldn't have escaped it by writing `\&` or `[&]`.

The solution chosen by the Perl developers was to use `(?...)` as the extension syntax. `?` immediately after a parenthesis was a syntax error because the `?` would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the `?` indicate what extension is being used, so `(?=foo)` is one thing (a positive lookahead assertion) and `(?:foo)` is something else (a non-capturing group containing the subexpression `foo`).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a `P`, you know that it's an extension that's specific to Python.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you'll want to use a group to denote a part of a regular expression, but aren't interested in retrieving the group's contents. You can make this fact explicit by using a non-capturing group: `(?:...)`, where you can replace the `...` with any other regular expression.

```
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can't retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as `*`, and nest it within other groups (capturing or non-capturing). `(?:...)` is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: `(?P<name>...)`. *name* is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The match object methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```
>>> p = re.compile(r'(?P<word>\b\w+\b)')
>>> m = p.search( '(((( Lots of punctuation )))' )
>>> m.group('word')
'Lots'
>>> m.group(1)
'Lots'
```

Additionally, you can retrieve named groups as a dictionary with **`groupdict()`**:

```
>>> m = re.match(r'(?P<first>\w+) (?P<last>\w+)', 'Jane
>>> m.groupdict()
{'first': 'Jane', 'last': 'Doe'}
```

Named groups are handy because they let you use easily remembered names, instead of having to remember numbers. Here's an example RE from the **imaplib** module:

```
InternalDate = re.compile(r'INTERNALDATE "'
        r'(?P<day>[ 123][0-9])-(?P<mon>[A-Z][a-z][a-z])-
        r'(?P<year>[0-9][0-9][0-9][0-9])'
        r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<
        r' (?P<zonen>[-+])(?P<zoneh>[0-9][0-9])(?P<zonem
        r'"')
```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(...)\1` refers to the number of the group. There's naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called *name* should again be matched at the current point. The regular expression for finding doubled words, `\b(\w+)\s+\1\b` can also be written as `\b(?P<word>\w+)\s+(?P=word)\b`:

```
>>> p = re.compile(r'\b(?P<word>\w+)\s+(?P=word)\b')
>>> p.search('Paris in the the spring').group()
'the the'
```

Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

`(?=...)`
: Positive lookahead assertion. This succeeds if the contained regular expression, represented here by `...`, successfully matches at the current location, and fails otherwise. But, once

the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

`(?!...)`
: Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression *doesn't* match at the current position in the string.

To make this concrete, let's look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a `.`. For example, in `news.rc`, `news` is the base name, and `rc` is the filename's extension.

The pattern to match this is quite simple:

```
.*[.].*$
```

Notice that the `.` needs to be treated specially because it's a metacharacter, so it's inside a character class to only match that specific character. Also notice the trailing `$`; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not `bat`? Some incorrect attempts:

`.*[.][^b].*$` The first attempt above tries to exclude `bat` by requiring that the first character of the extension is not a `b`. This is wrong, because the pattern also doesn't match `foo.bar`.

```
.*[.]([^b]..|.[^a].|..[^t])$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn't `b`; the second character isn't `a`; or the third character isn't `t`. This accepts `foo.bar` and rejects `autoexec.bat`, but it requires a three-letter extension and won't

accept a filename with a two-letter extension such as `sendmail.cf`. We'll complicate the pattern again in an effort to fix it.

```
.*[.]([^b].?.?|.[^a]?.?|..?[^t]?)$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as `sendmail.cf`.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both `bat` and `exe` as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

`.*[.](?!bat$)[^.]*$` The negative lookahead means: if the expression `bat` doesn't match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed. The `[^.]*` makes sure that the pattern works when there are multiple dots in the filename.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](?!bat$|exe$)[^.]*$
```

Modifying Strings

Up to this point, we've simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

Method/Attribute	Purpose
`split()`	Split the string into a list, splitting it wherever the RE matches
`sub()`	Find all substrings where the RE matches, and replace them with a different string

Does the same thing as **`sub()`**, but returns the new string and the number of replacements

Splitting Strings

The **`split()`** method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It's similar to the **`split()`** method of strings but provides much more generality in the delimiters that you can split by; string **`split()`** only supports splitting by whitespace or by a fixed string. As you'd expect, there's a module-level **`re.split()`** function, too.

.split(*string*[, *maxsplit*=*0*])

> Split *string* by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits are performed.

You can limit the number of splits made, by passing a value for *maxsplit*. When *maxsplit* is nonzero, at most *maxsplit* splits will be made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split()
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of
>>> p.split('This is a test, short and sweet, of split()
['This', 'is', 'a', 'test, short and sweet, of split().'
```

Sometimes you're not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
```

```
>>> p2.split('This... is a test.')
['This', '... ', 'is', ' ', 'a', ' ', 'test', '.', '']
```

The module-level function **`re.split()`** adds the RE to be used as the first argument, but is otherwise the same.

```
>>> re.split(r'[\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split(r'([\W]+)', 'Words, words, words.')
['Words', ', ', 'words', ', ', 'words', '.', '']
>>> re.split(r'[\W]+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The **`sub()`** method takes a replacement value, which can be either a string or a function, and the string to be processed.

.sub(*replacement*, *string*[, *count*=*0*])

> Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in *string* by the replacement *replacement*. If the pattern isn't found, *string* is returned unchanged.
>
> The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here's a simple example of using the **`sub()`** method. It replaces colour names with the word `colour`:

```
>>> p = re.compile('(blue|white|red)')
>>> p.sub('colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub('colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The **`subn()`** method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```
>>> p = re.compile('(blue|white|red)')
>>> p.subn('colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn('colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they're not adjacent to a previous empty match.

```
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b--d-'
```

If *replacement* is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\&` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{, }`, and changes `section` to `subsection`:

```
>>> p = re.compile('section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First} section{secc
'subsection{First} subsection{second}'
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0`. (`\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```
>>> p = re.compile('section{ (?P<name> [^}]* ) }', re.VE
>>> p.sub(r'subsection{\1}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}','section{First}')
'subsection{First}'
```

replacement can also be a function, which gives you even more control. If *replacement* is a function, the function is called for every non-overlapping occurrence of *pattern*. On each call, the function is passed a match object argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for u
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level **`re.sub()`** function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `'x x'`.

Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn't intuitive and at times they don't behave the way you may expect them to. This section will point out

some of the most common pitfalls.

Use String Methods

Sometimes using the **re** module is a mistake. If you're matching a fixed string, or a single character class, and you're not using any **re** features such as the **IGNORECASE** flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they're usually much faster, because the implementation is a single small C loop that's been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. **re.sub()** seems like the function to use for this, but consider the **replace()** method. Note that **replace()** will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond **replace()**'s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like `re.sub('\n', ' ', S)`, but **translate()** is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the **re** module, consider whether your problem can be solved with a faster and simpler string method.

match() versus search()

The **match()** function only checks if the RE matches at the beginning of the string while **search()** will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, **match()** will only report a successful match which will start at 0; if the match wouldn't start at zero, **match()** will *not* report it.

```
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, **`search()`** will scan forward through the string, reporting the first match it finds.

```
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using **`re.match()`**, and just add `.*` to the front of your RE. Resist this temptation and use **`re.search()`** instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Crow` must match starting with a `'C'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'C'` is found.

Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use **`re.search()`** instead.

Greedy versus Non-Greedy

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of `.*`.

```
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
```

```
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the `'<'` in `'<html>'`, and the `.*` consumes the rest of the string. There's still more left in the RE, though, and the `>` can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `'<'` in `'<html>'` to the `'>'` in `'</title>'`, which isn't what you want.

In this case, the solution is to use the non-greedy quantifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as *little* text as possible. In the above example, the `'>'` is tried immediately after the first `'<'` matches, and when it fails, the engine advances a character at a time, retrying the `'>'` at every step. This produces just the right result:

```
>>> print(re.match('<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be *very* complicated. Use an HTML or XML parser module for such tasks.)

Using re.VERBOSE

By now you've probably noticed that regular expressions are a very compact notation, but they're not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the **`re.VERBOSE`** flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the

regular expression that *isn't* inside a character class is ignored. This means that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters `'a'`, `'b'`, or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```
pat = re.compile(r"""
 \s*                 # Skip leading whitespace
 (?P<header>[^:]+)   # Header name
 \s* :               # Whitespace, and a colon
 (?P<value>.*?)      # The header's value -- *? used to
                     # lose the following trailing white
 \s*$                # Trailing whitespace to end-of-lin
""", re.VERBOSE)
```

This is far more readable than:

```
pat = re.compile(r"\s*(?P<header>[^:]+)\s*:(?P<value>.*?
```

Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed **`regex`** module, which won't help you much.) Consider checking it out from your library.

Socket Programming HOWTO

Author

Gordon McMillan

Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It's not really a tutorial - you'll still have work to do in getting things operational. It doesn't cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

Sockets

I'm only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I'll only talk about STREAM (i.e. TCP) sockets - unless you really know what you're doing (in which case this HOWTO isn't for you!), you'll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I'll start by talking about blocking sockets. You'll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that "socket" can mean a number of subtly different things, depending on context. So first, let's make a distinction between a "client" socket - an endpoint of a conversation, and a "server" socket, which is more like a switchboard operator. The client application (your browser, for example) uses "client" sockets exclusively; the web server it's talking to uses both "server" sockets and "client" sockets.

History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).

Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal
s.connect(("www.python.org", 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That's right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a "server socket":

```
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET, socket.SOCK
# bind the socket to a public host, and a well-known por
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so

that the socket would be visible to the outside world. If we had used `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a "server" socket, but one that was only visible within the same machine. `s.bind(('', 80))` specifies that the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for "well known" services (HTTP, SNMP etc). If you're playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a "server" socket, listening on port 80, we can enter the mainloop of the web server:

```
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded ser
    ct = client_thread(clientsocket)
    ct.run()
```

There's actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our "server" socket and any active `clientsocket`s using `select`. More about that later. The important thing to understand now is this: this is *all* a "server" socket does. It doesn't send any data. It doesn't receive any data. It just produces "client" sockets. Each `clientsocket` is created in response to some *other* "client" socket doing a `connect()` to the host and port we're bound to. As soon as we've created that `clientsocket`, we go back to listening for more connections. The two "clients" are free to chat it up - they are using some dynamically allocated port which will be recycled when the

conversation ends.

IPC

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF_INET sockets, bind the "server" socket to `'localhost'`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

See also

The **`multiprocessing`** integrates cross-platform IPC into a higher-level API.

Using a Socket

The first thing to note, is that the web browser's "client" socket and the web server's "client" socket are identical beasts. That is, this is a "peer to peer" conversation. Or to put it another way, *as the designer, you will have to decide what the rules of etiquette are for a conversation*. Normally, the `connect`ing socket starts the conversation, by sending in a request, or perhaps a signon. But that's a design decision - it's not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use `send` and `recv`, or you can transform your client socket into a file-like beast and use `read` and `write`. The latter is the way Java presents its sockets. I'm not going to talk about it here, except to warn you that you need to use `flush` on sockets. These are buffered "files", and a common mistake is to `write` something, and then `read` for a reply. Without a `flush` in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - `send` and `recv` operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they

return when the associated network buffers have been filled (`send`) or emptied (`recv`). They then tell you how many bytes they handled. It is *your* responsibility to call them again until your message has been completely dealt with.

When a `recv` returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I'll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That's it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that *there is no* EOT *on a socket.* I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has *not* been broken, you may wait on a `recv` forever, because the socket will *not* tell you that there's nothing more to read (for now). Now if you think about that a bit, you'll come to realize a fundamental truth of sockets: *messages must either be fixed length* (yuck), *or be delimited* (shrug), *or indicate how long they are* (much better), *or end by shutting down the connection*. The choice is entirely yours, (but some ways are righter than others).

Assuming you don't want to end the connection, the simplest solution is a fixed length message:

```
class MySocket:
    """demonstration class only
      - coded for clarity, not efficiency
    """

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(
                            socket.AF_INET, socket.SOCK_
        else:
```

```
            self.sock = sock

    def connect(self, host, port):
        self.sock.connect((host, port))

    def mysend(self, msg):
        totalsent = 0
        while totalsent < MSGLEN:
            sent = self.sock.send(msg[totalsent:])
            if sent == 0:
                raise RuntimeError("socket connection br
            totalsent = totalsent + sent

    def myreceive(self):
        chunks = []
        bytes_recd = 0
        while bytes_recd < MSGLEN:
            chunk = self.sock.recv(min(MSGLEN - bytes_re
            if chunk == b'':
                raise RuntimeError("socket connection br
            chunks.append(chunk)
            bytes_recd = bytes_recd + len(chunk)
        return b''.join(chunks)
```

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded `\0` characters). It's mostly the receiving code that gets more complex. (And in C, it's not much worse, except you can't use `strlen` if the message has embedded `\0`s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you'll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you've received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with its length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

Binary Data

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, network byte order [https://en.wikipedia.org/wiki/Endianness#Networking] is big-endian, with the most significant byte first, so a 16 bit integer with the value `1` would be the two hex bytes `00 01`. However, most common processors (x86/AMD64, ARM, RISC-V), are little-endian, with the least significant byte first - that same `1` would be `01 00`.

Socket libraries have calls for converting 16 and 32 bit integers - `ntohl, htonl, ntohs, htons` where "n" means *network* and "h" means *host*, "s" means *short* and "l" means *long*. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 64-bit machines, the ASCII representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, most integers have the value 0, or maybe 1. The string `"0"` would be two bytes, while a

full 64-bit integer would be 8. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.

Disconnecting

Strictly speaking, you're supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean "I'm not going to send anymore, but I'll still listen", or "I'm not listening, good riddance!". Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server "This client is done sending, but can still receive." The server can detect "EOF" by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it's needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you're just being slow. *Please* `close` your sockets when you're done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you're using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn't really consuming much in the way of resources. Do *not* try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated

with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.

Non-blocking Sockets

If you've understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(False)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable POSIX flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don't believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let's skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C:

```
ready_to_read, ready_to_write, in_error = \
               select.select(
                  potential_readers,
                  potential_writers,
                  potential_errs,
                  timeout)
```

You pass `select` three lists: the first contains all sockets that you

might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return *something*. Same idea for the writable list. You'll be able to send *something*. Maybe not all you want to, but *something* is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a "server" socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It's one way of determining whether you will block - the socket returns as readable when there's something in the buffers. However, this still doesn't help with the problem of determining whether the other end is done, or just busy with something else.

Portability alert: On Unix, `select` works both with the sockets and files. Don't try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.

Sorting HOW TO

Author

Andrew Dalke and Raymond Hettinger

Release

0.1

Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.

Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```
>>> sorted({1: 'D', 2: 'B', 3: 'B', 4: 'E', 5: 'A'})
[1, 2, 3, 4, 5]
```

Key Functions

Both `list.sort()` and `sorted()` have a *key* parameter to specify a function (or other callable) to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison:

```
>>> sorted("This is a test string from Andrew".split(),
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This']
```

The value of the *key* parameter should be a function (or other callable) that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```
>>> student_tuples = [
...     ('john', 'A', 15),
...     ('jane', 'B', 12),
...     ('dave', 'B', 10),
... ]
>>> sorted(student_tuples, key=lambda student: student[2
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)
```

The same technique works for objects with named attributes. For example:

```
>>> class Student:
...     def __init__(self, name, grade, age):
...         self.name = name
...         self.grade = grade
...         self.age = age
...     def __repr__(self):
...         return repr((self.name, self.grade, self.age
```

```
>>> student_objects = [
...     Student('john', 'A', 15),
...     Student('jane', 'B', 12),
...     Student('dave', 'B', 10),
... ]
>>> sorted(student_objects, key=lambda student: student.
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)
```

Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The **`operator`** module has **`itemgetter()`**, **`attrgetter()`**, and a **`methodcaller()`** function.

Using those functions, the above examples become simpler and faster:

```
>>> from operator import itemgetter, attrgetter

>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)

>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)
```

The operator module functions allow multiple levels of sorting. For example, to sort by *grade* then by *age*:

```
>>> sorted(student_tuples, key=itemgetter(1,2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)

>>> sorted(student_objects, key=attrgetter('grade', 'age
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)
```

Ascending and Descending

Both **`list.sort()`** and **`sorted()`** accept a *reverse* parameter

with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse *age* order:

```
>>> sorted(student_tuples, key=itemgetter(2), reverse=Tr
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)

>>> sorted(student_objects, key=attrgetter('age'), rever
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)
```

Sort Stability and Complex Sorts

Sorts are guaranteed to be stable [https://en.wikipedia.org/wiki/Sorting_algorithm#Stability]. That means that when multiple records have the same key, their original order is preserved.

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue'
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for *blue* retain their original order so that `('blue', 1)` is guaranteed to precede `('blue', 2)`.

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending *grade* and then ascending *age*, do the *age* sort first and then sort again using *grade*:

```
>>> s = sorted(student_objects, key=attrgetter('age'))
>>> sorted(s, key=attrgetter('grade'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)
```

This can be abstracted out into a wrapper function that can take a list and tuples of field and order to sort them on multiple passes.

```
>>> def multisort(xs, specs):
...     for key, reverse in reversed(specs):
...         xs.sort(key=attrgetter(key), reverse=reverse
...     return xs

>>> multisort(list(student_objects), (('grade', True), (
```

```
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)
```

The Timsort [https://en.wikipedia.org/wiki/Timsort] algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.

Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by *grade* using the DSU approach:

```
>>> decorated = [(student.grade, i, student) for i, stuc
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index *i* in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.

Another name for this idiom is Schwartzian transform [https://en.wikipedia.org/wiki/Schwartzian_transform], after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.

Comparison Functions

Unlike key functions that return an absolute value for sorting, a comparison function computes the relative ordering for two inputs.

For example, a balance scale [https://upload.wikimedia.org/wikipedia/commons/1/17/Balance_à_tabac_1850.JPG] compares two samples giving a relative ordering: lighter, equal, or heavier. Likewise, a comparison function such as `cmp(a, b)` will return a negative value for less-than, zero if the inputs are equal, or a positive value for greater-than.

It is common to encounter comparison functions when translating algorithms from other languages. Also, some libraries provide comparison functions as part of their API. For example, **`locale.strcoll()`** is a comparison function.

To accommodate those situations, Python provides **`functools.cmp_to_key`** to wrap the comparison function to make it usable as a key function:

```
sorted(words, key=cmp_to_key(strcoll))  # locale-aware s
```

Odds and Ends

- For locale aware sorting, use **`locale.strxfrm()`** for a key function or **`locale.strcoll()`** for a comparison function. This is necessary because “alphabetical” sort orderings can vary across cultures even if the underlying alphabet is the same.

- The *reverse* parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin **`reversed()`** function twice:

  ```
  >>> data = [('red', 1), ('blue', 1), ('red', 2), ('
  ```

```
>>> standard_way = sorted(data, key=itemgetter(0),
>>> double_reversed = list(reversed(sorted(reversed
>>> assert standard_way == double_reversed
>>> standard_way
[('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
```

- The sort routines use `<` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an **`__lt__()`** method:

  ```
  >>> Student.__lt__ = lambda self, other: self.age <
  >>> sorted(student_objects)
  [('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A'
  ```

  However, note that `<` can fall back to using **`__gt__()`** if **`__lt__()`** is not implemented (see **`object.__lt__()`**).

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

  ```
  >>> students = ['dave', 'john', 'jane']
  >>> newgrades = {'john': 'F', 'jane':'A', 'dave': '
  >>> sorted(students, key=newgrades.__getitem__)
  ['jane', 'dave', 'john']
  ```

Unicode HOWTO

Release
1.12

This HOWTO discusses Python's support for the Unicode specification for representing textual data, and explains various problems that people commonly encounter when trying to work with Unicode.

Introduction to Unicode

Definitions

Today's programs need to be able to handle a wide variety of characters. Applications are often internationalized to display messages and output in a variety of user-selectable languages; the same program might need to output an error message in English, French, Japanese, Hebrew, or Russian. Web content can be written in any of these languages and can also include a variety of emoji symbols. Python's string type uses the Unicode Standard for representing characters, which lets Python programs work with all these different possible characters.

Unicode (https://www.unicode.org/) is a specification that aims to list every character used by human languages and give each character its own unique code. The Unicode specifications are continually revised and updated to add new languages and symbols.

A **character** is the smallest possible component of a text. 'A', 'B', 'C', etc., are all different characters. So are 'È' and 'Í'. Characters vary depending on the language or context you're talking about. For example, there's a character for "Roman Numeral One", 'I', that's separate from the uppercase letter 'I'. They'll usually look the same, but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point value is an integer in the range 0 to 0x10FFFF (about 1.1 million values, the actual number assigned [https://www.unicode.org/versions/latest/#Summary] is less than that). In the standard and in this document, a code point is written using the notation `U+265E` to mean the character with value `0x265e` (9,822 in decimal).

The Unicode standard contains a lot of tables listing characters and their corresponding code points:

```
0061    'a'; LATIN SMALL LETTER A
0062    'b'; LATIN SMALL LETTER B
0063    'c'; LATIN SMALL LETTER C
...
007B    '{'; LEFT CURLY BRACKET
...
2167    'Ⅷ'; ROMAN NUMERAL EIGHT
2168    'Ⅸ'; ROMAN NUMERAL NINE
...
265E    '♞'; BLACK CHESS KNIGHT
265F    '♟'; BLACK CHESS PAWN
...
1F600   '😀'; GRINNING FACE
1F609   '😉'; WINKING FACE
...
```

Strictly, these definitions imply that it's meaningless to say 'this is character `U+265E`'. `U+265E` is a code point, which represents some particular character; in this case, it represents the character 'BLACK CHESS KNIGHT', '♞'. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through `0x10FFFF` (1,114,111 decimal). This sequence of code points needs to be represented in memory as a set of **code units**, and **code units** are then mapped to 8-bit bytes. The rules for translating a Unicode string into a sequence of bytes are called a **character encoding**, or just an **encoding**.

The first encoding you might think of is using 32-bit integers as the code unit, and then using the CPU's representation of 32-bit integers. In this representation, the string "Python" might look like this:

```
   P           y           t           h           o
0x50 00 00 00 79 00 00 00 74 00 00 00 68 00 00 00 6f 00
   0  1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17
```

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by `0x00` bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn't matter too much (desktop computers have gigabytes of RAM, and strings aren't usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It's not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

Therefore this encoding isn't used very much, and people instead choose other encodings that are more efficient and convenient, such as UTF-8.

UTF-8 is one of the most commonly used encodings, and Python

often defaults to using it. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit values are used in the encoding. (There are also UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128, it’s represented by the corresponding byte value.
2. If the code point is $>= 128$, it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a sequence of bytes that contains embedded zero bytes only where they represent the null character (U+0000). This means that UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes for anything other than end-of-string markers.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.
6. UTF-8 is a byte oriented encoding. The encoding specifies that each character is represented by a specific sequence of one or more bytes. This avoids the byte-ordering issues that can occur with integer and word oriented encodings, like UTF-16 and UTF-32, where the sequence of bytes varies depending on the hardware on which the string was encoded.

References

The Unicode Consortium site [https://www.unicode.org] has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. A chronology [https://

www.unicode.org/history/] of the origin and development of Unicode is also available on the site.

On the Computerphile Youtube channel, Tom Scott briefly discusses the history of Unicode and UTF-8 [https://www.youtube.com/watch?v=MijmeoH9LT4] (9 minutes 36 seconds).

To help understand the standard, Jukka Korpela has written an introductory guide [https://jkorpela.fi/unicode/guide.html] to reading the Unicode character tables.

Another good introductory article [https://www.joelonsoftware.com/2003/10/08/the-absolute-minimum-every-software-developer-absolutely-positively-must-know-about-unicode-and-character-sets-no-excuses/] was written by Joel Spolsky. If this introduction didn't make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for "character encoding [https://en.wikipedia.org/wiki/Character_encoding]" and UTF-8 [https://en.wikipedia.org/wiki/UTF-8], for example.

Python's Unicode Support

Now that you've learned the rudiments of Unicode, we can look at Python's Unicode features.

The String Type

Since Python 3.0, the language's **`str`** type contains Unicode characters, meaning any string created using `"unicode rocks!"`, `'unicode rocks!'`, or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
```

```
except OSError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
    f.write("test\n")
```

If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```
>>> "\N{GREEK CAPITAL LETTER DELTA}"  # Using the charac
'\u0394'
>>> "\u0394"                          # Using a 16-bit h
'\u0394'
>>> "\U00000394"                      # Using a 32-bit h
'\u0394'
```

In addition, one can create a string using the **`decode()`** method of **`bytes`**. This method takes an *encoding* argument, such as `UTF-8`, and optionally an *errors* argument.

The *errors* argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are `'strict'` (raise a **`UnicodeDecodeError`** exception), `'replace'` (use `U+FFFD, REPLACEMENT CHARACTER`), `'ignore'` (just leave the character out of the Unicode result), or `'backslashreplace'` (inserts a `\xNN` escape sequence). The following examples show the differences:

```
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
    ...
UnicodeDecodeError: 'utf-8' codec can't decode byte 0x80
  invalid start byte
```

```
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "backslashreplace")
'\\x80abc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```

Encodings are specified as strings containing the encoding's name. Python comes with roughly 100 different encodings; see the Python Library Reference at Standard Encodings for a list. Some encodings have multiple names; for example, `'latin-1'`, `'iso_8859_1'` and `'8859'` are all synonyms for the same encoding.

One-character Unicode strings can also be created with the **`chr()`** built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in **`ord()`** function that takes a one-character Unicode string and returns the code point value:

```
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

Converting to Bytes

The opposite method of **`bytes.decode()`** is **`str.encode()`**, which returns a **`bytes`** representation of the Unicode string, encoded in the requested *encoding*.

The *errors* parameter is the same as the parameter of the **`decode()`** method but supports a few more possible handlers. As well as `'strict'`, `'ignore'`, and `'replace'` (which in this case inserts a question mark instead of the unencodable character), there is also `'xmlcharrefreplace'` (inserts an XML character reference), `backslashreplace` (inserts a `\uNNNN` escape sequence) and `namereplace` (inserts a `\N{...}` escape sequence).

The following example shows the different results:

```
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
    ...
UnicodeEncodeError: 'ascii' codec can't encode character
  position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'&#40960;abcd &#1972;'
>>> u.encode('ascii', 'backslashreplace')
b'\\ua000abcd\\u07b4'
>>> u.encode('ascii', 'namereplace')
b'\\N{YI SYLLABLE IT}abcd\\u07b4'
```

The low-level routines for registering and accessing the available encodings are found in the **codecs** module. Implementing new encodings also requires understanding the **codecs** module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won't be covered in this HOWTO.

Unicode Literals in Python Source Code

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```
>>> s = "a\xac\u1234\u20ac\U00008000"
... #     ^^^^ two-digit hex escape
... #         ^^^^^^ four-digit Unicode escape
... #                     ^^^^^^^^^^ eight-digit Unicode
>>> [ord(c) for c in s]
```

```
[97, 172, 4660, 8364, 32768]
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you're using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the **`chr()`** built-in function, but this is even more tedious.

Ideally, you'd want to be able to write literals in your language's natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The `-*-` symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be UTF-8 as already mentioned. See also **PEP 263** [https://peps.python.org/pep-0263/] for more information.

Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character's name, its category, the numeric value if applicable

(for characters representing numeric concepts such as the Roman numerals, fractions such as one-third and four-fifths, etc.). There are also display-related properties, such as how to use the code point in bidirectional text.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) + chr

for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c), e
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, `'Ll'` means ‘Letter, lowercase’, `'No'` means “Number, other”, `'Mn'` is “Mark, nonspacing”, and `'So'` is “Symbol, other”. See the General Category Values section of the Unicode Character Database documentation [https://www.unicode.org/reports/tr44/#General_Category_Values] for a list of category codes.

Comparing Strings

Unicode adds some complication to comparing strings, because the same set of characters can be represented by different sequences of code points. For example, a letter like 'ê' can be represented as a single code point U+00EA, or as U+0065 U+0302, which is the code point for 'e' followed by a code point for 'COMBINING CIRCUMFLEX ACCENT'. These will produce the same output when printed, but one is a string of length 1 and the other is of length 2.

One tool for a case-insensitive comparison is the **`casefold()`** string method that converts a string to a case-insensitive form following an algorithm described by the Unicode Standard. This algorithm has special handling for characters such as the German letter 'ß' (code point U+00DF), which becomes the pair of lowercase letters 'ss'.

```
>>> street = 'Gürzenichstraße'
>>> street.casefold()
'gürzenichstrasse'
```

A second tool is the **`unicodedata`** module's **`normalize()`** function that converts strings to one of several normal forms, where letters followed by a combining character are replaced with single characters. **`normalize()`** can be used to perform string comparisons that won't falsely report inequality if two strings use combining characters differently:

```
import unicodedata

def compare_strs(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(s1) == NFD(s2)

single_char = 'ê'
multiple_chars = '\N{LATIN SMALL LETTER E}\N{COMBINING C
print('length of first string=', len(single_char))
print('length of second string=', len(multiple_chars))
print(compare_strs(single_char, multiple_chars))
```

When run, this outputs:

```
$ python3 compare-strs.py
length of first string= 1
length of second string= 2
True
```

The first argument to the **`normalize()`** function is a string giving the desired normalization form, which can be one of 'NFC', 'NFKC', 'NFD', and 'NFKD'.

The Unicode Standard also specifies how to do caseless comparisons:

```
import unicodedata

def compare_caseless(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(NFD(s1).casefold()) == NFD(NFD(s2).casefo

# Example usage
single_char = 'ê'
multiple_chars = '\N{LATIN CAPITAL LETTER E}\N{COMBINING

print(compare_caseless(single_char, multiple_chars))
```

This will print `True`. (Why is **`NFD()`** invoked twice? Because there are a few characters that make **`casefold()`** return a non-normalized string, so the result needs to be normalized again. See section 3.13 of the Unicode Standard for a discussion and an example.)

Unicode Regular Expressions

The regular expressions supported by the **`re`** module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example,

`\d` will match the characters `[0-9]` in bytes but in strings will match any character that's in the `'Nd'` category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```
import re
p = re.compile(r'\d+')

s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))
```

When executed, `\d+` will match the Thai numerals and print them out. If you supply the **`re.ASCII`** flag to **`compile()`**, `\d+` will match the substring "57" instead.

Similarly, `\w` matches a wide variety of Unicode characters but only `[a-zA-Z0-9_]` in bytes or if **`re.ASCII`** is supplied, and `\s` will match either Unicode whitespace characters or `[ \t\n\r\f\v]`.

Marc-André Lemburg gave a presentation titled "Python and Unicode" (PDF slides) [https://downloads.egenix.com/python/Unicode-

EPC2002-Talk.pdf] at EuroPython 2002. The slides are an excellent overview of the design of Python 2's Unicode features (where the Unicode string type is called `unicode` and literals start with `u`).

Reading and Writing Unicode Data

Once you've written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It's possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It's possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you'd need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the built-in **`open()`** function can return a file-like object that assumes the file's

contents are in a specified encoding and accepts Unicode parameters for methods such as **`read()`** and **`write()`**. This works through **`open()`**'s *encoding* and *errors* parameters which are interpreted just like those in **`str.encode()`** and **`bytes.decode()`**.

Reading Unicode from a file is therefore simple:

```
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('\u4500 blah blah blah\n')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don't skip the BOM.

In some areas, it is also convention to use a "BOM" at the start of UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. For reading such files, use the 'utf-8-sig' codec to automatically skip the mark if present.

Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is

implemented by converting the Unicode string into some encoding that varies depending on the system. Today Python is converging on using UTF-8: Python on MacOS has used UTF-8 for several versions, and Python 3.6 switched to using UTF-8 on Windows as well. On Unix systems, there will only be a filesystem encoding. if you've set the `LANG` or `LC_CTYPE` environment variables; if you haven't, the default encoding is again UTF-8.

The **`sys.getfilesystemencoding()`** function returns the encoding to use on your current system, in case you want to do the encoding manually, but there's not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah\n')
```

Functions in the **`os`** module such as **`os.stat()`** will also accept Unicode filenames.

The **`os.listdir()`** function returns filenames, which raises an issue: should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? **`os.listdir()`** can do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
$ python listdir-test.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, you should can just stick with using Unicode with these APIs. The bytes APIs should only be used on systems where undecodable file names can be present; that's pretty much only Unix systems now.

Tips for Writing Unicode-aware Programs

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

> Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a **`TypeError`** will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you're doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

Converting Between File Encodings

The `StreamRecoder` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file *f* that's in Latin-1, you can wrap it with a `StreamRecoder` to return bytes encoded in UTF-8:

```
new_f = codecs.StreamRecoder(f,
    # en/decoder: used by read() to encode its results a
    # by write() to decode its input.
    codecs.getencoder('utf-8'), codecs.getdecoder('utf-8

    # reader/writer: used to read and write to the strea
    codecs.getreader('latin-1'), codecs.getwriter('latin
```

Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the `surrogateescape` error handler:

```
with open(fname, 'r', encoding="ascii", errors="surrogat
    data = f.read()

# make changes to the string 'data'

with open(fname + '.new', 'w',
          encoding="ascii", errors="surrogateescape") as
    f.write(data)
```

The `surrogateescape` error handler will decode any non-ASCII bytes as code points in a special range running from U+DC80 to U+DCFF. These code points will then turn back into the same bytes when the `surrogateescape` error handler is used to encode the data and write it back out.

HOWTO Fetch Internet Resources Using The urllib Package

Author

Michael Foord [https://agileabstractions.com/]

Note

There is a French translation of an earlier revision of this HOWTO, available at urllib2 - Le Manuel manquant [https://web.archive.org/web/20200910051922/http://www.voidspace.org.uk/python/articles/urllib2_francais.shtml].

Introduction

Related Articles

You may also find useful the following article on fetching web resources with Python:

- Basic Authentication [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml]

  A tutorial on *Basic Authentication*, with examples in Python.

urllib.request is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called

handlers and openers.

urllib.request supports fetching URLs for many “URL schemes” (identified by the string before the `":"` in URL - for example `"ftp"` is the URL scheme of `"ftp://python.org/"`) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html]. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the **`urllib.request`** docs, but is supplementary to them.

Fetching URLs

The simplest way to use urllib.request is as follows:

```
import urllib.request
with urllib.request.urlopen('http://python.org/') as res
   html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the **`shutil.copyfileobj()`** and **`tempfile.NamedTemporaryFile()`** functions:

```
import shutil
import tempfile
import urllib.request

with urllib.request.urlopen('http://python.org/') as res
    with tempfile.NamedTemporaryFile(delete=False) as tm
        shutil.copyfileobj(response, tmp_file)

with open(tmp_file.name) as html:
```

```
    pass
```

Many uses of urllib will be that simple (note that instead of an 'http:' URL we could have used a URL starting with 'ftp:', 'file:', etc.). However, it's the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib.request mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```
import urllib.request

req = urllib.request.Request('http://www.voidspace.org.u
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

Note that urllib.request makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

```
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that Request objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information ("metadata") *about* the data or about the request itself, to the server - this information is sent as HTTP "headers". Let's look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what's known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs

have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the `data` argument. The encoding is done using a function from the **`urllib.parse`** library.

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }

data = urllib.parse.urlencode(values)
data = data.encode('ascii') # data should be bytes
req = urllib.request.Request(url, data)
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission [https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13] for more details).

If you do not pass the `data` argument, urllib uses a **GET** request. One way in which GET and POST requests differ is that POST requests often have "side-effects": they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to *always* cause side-effects, and GET requests *never* to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```
>>> import urllib.request
```

```
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.parse.urlencode(data)
>>> print(url_values)  # The order may differ from below
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib.request.urlopen(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

Headers

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites 1 dislike being browsed by programs, or send different versions to different browsers 2. By default urllib identifies itself as `Python-urllib/x.y` (where `x` and `y` are the major and minor version numbers of the Python release, e.g. `Python-urllib/2.5`), which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header 3. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer 4.

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/5.0 (Windows NT 6.1; Win64; x64)'
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python' }
headers = {'User-Agent': user_agent}
```

```
data = urllib.parse.urlencode(values)
data = data.encode('ascii')
req = urllib.request.Request(url, data, headers)
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.

Handling Exceptions

urlopen raises **`URLError`** when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as **`ValueError`**, **`TypeError`** etc. may also be raised).

`HTTPError` is the subclass of **`URLError`** raised in the specific case of HTTP URLs.

The exception classes are exported from the **`urllib.error`** module.

URLError

Often, URLError is raised because there is no network connection (no route to the specified server), or the specified server doesn't exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```
>>> req = urllib.request.Request('http://www.pretend_ser
>>> try: urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...     print(e.reason)
...
(4, 'getaddrinfo failed')
```

HTTPError

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, urllib will handle that for you). For those it can’t handle, urlopen will raise an **`HTTPError`**. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html] for a reference on all the HTTP error codes.

The **`HTTPError`** instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100–299 range indicate success, you will usually only see error codes in the 400–599 range.

`http.server.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes in that shows all the response codes used by **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html]. The dictionary is reproduced here for convenience

```
# Table mapping response codes to messages; entries have

```
    413: ('Request Entity Too Large', 'Entity is too lar
    414: ('Request-URI Too Long', 'URI is too long.'),
    415: ('Unsupported Media Type', 'Entity body in unsu
    416: ('Requested Range Not Satisfiable',
          'Cannot satisfy request range.'),
    417: ('Expectation Failed',
          'Expect condition could not be satisfied.'),

    500: ('Internal Server Error', 'Server got itself in
    501: ('Not Implemented',
          'Server does not support this operation'),
    502: ('Bad Gateway', 'Invalid responses from another
    503: ('Service Unavailable',
          'The server cannot process the request due to
    504: ('Gateway Timeout',
          'The gateway server did not receive a timely r
    505: ('HTTP Version Not Supported', 'Cannot fulfill
    }
```

When an error is raised the server responds by returning an HTTP error code *and* an error page. You can use the **`HTTPError`** instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the `urllib.response` module:

```
>>> req = urllib.request.Request('http://www.python.org/
>>> try:
...     urllib.request.urlopen(req)
... except urllib.error.HTTPError as e:
...     print(e.code)
...     print(e.read())
...
404
b'<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitio
  "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.d
  ...
  <title>Page Not Found</title>\n
  ...
```

Wrapping it Up

So if you want to be prepared for **`HTTPError`** *or* **`URLError`** there are two basic approaches. I prefer the second approach.

Number 1

```
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.')
    print('Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.')
    print('Reason: ', e.reason)
else:
    # everything is fine
```

Note

The `except HTTPError` *must* come first, otherwise `except URLError` will *also* catch an **`HTTPError`**.

Number 2

```
from urllib.request import Request, urlopen
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
```

```
        print('The server couldn\'t fulfill the request.
        print('Error code: ', e.code)
else:
    # everything is fine
```

info and geturl

The response returned by urlopen (or the **`HTTPError`** instance) has two useful methods **`info()`** and **`geturl()`** and is defined in the module **`urllib.response`**..

geturl - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

info - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an **`http.client.HTTPMessage`** instance.

Typical headers include 'Content-length', 'Content-type', and so on. See the Quick Reference to HTTP Headers [https://jkorpela.fi/http.html] for a useful listing of HTTP headers with brief explanations of their meaning and use.

Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly named **`urllib.request.OpenerDirector`**). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the "heavy lifting" is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle

redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.

Basic Authentication

To illustrate creating and installing a handler we will use the `HTTPBasicAuthHandler`. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial [http://www.voidspace.org.uk/python/articles/authentication.shtml].

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a 'realm'. The header looks like: `WWW-Authenticate: SCHEME realm="REALM"`.

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request.

This is ‘basic authentication’. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a `HTTPPasswordMgr`. Frequently one doesn’t care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to .add_password() will also match.

```
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefault

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username,

handler = urllib.request.HTTPBasicAuthHandler(password_m

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener
urllib.request.install_opener(opener)
```

Note

In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default openers have the handlers for normal situations – `ProxyHandler` (if a proxy setting such as an **`http_proxy`** environment variable is set), `UnknownHandler`, `HTTPHandler`, `HTTPDefaultErrorHandler`, `HTTPRedirectHandler`, `FTPHandler`, `FileHandler`, `DataHandler`, `HTTPErrorProcessor`.

`top_level_url` is in fact *either* a full URL (including the 'http:' scheme component and the hostname and optionally the port number) e.g. `"http://example.com/"` *or* an "authority" (i.e. the hostname, optionally including the port number) e.g. `"example.com"` or `"example.com:8080"` (the latter example includes a port number). The authority, if present, must NOT contain the "userinfo" component - for example `"joe:password@example.com"` is not correct.

Proxies

urllib will auto-detect your proxy settings and use those. This is through the `ProxyHandler`, which is part of the normal handler chain when a proxy setting is detected. Normally that's a good thing, but there are occasions when it may not be helpful 5. One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a Basic Authentication [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml] handler:

```
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

Note

Currently `urllib.request` *does not* support fetching of `https` locations through a proxy. However, this can be enabled

by extending urllib.request as shown in the recipe 6.

Note

`HTTP_PROXY` will be ignored if a variable `REQUEST_METHOD` is set; see the documentation on **`getproxies()`**.

Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the **`http.client`** library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has *no timeout* and can hang. Currently, the socket timeout is not exposed at the http.client or urllib.request levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the defau
# we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.u
response = urllib.request.urlopen(req)
```

Footnotes

This document was reviewed and revised by John Lee.

1

Google for example.

2

Browser sniffing is a very bad practice for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

3

The user agent for MSIE 6 is *'Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)'*

4

For details of more HTTP request headers, see Quick Reference to HTTP Headers [https://jkorpela.fi/http.html].

5

In my case I have to use a proxy to access the internet at work. If you attempt to fetch *localhost* URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

Argparse Tutorial

author

Tshepang Lekhonkhobe

This tutorial is intended to be a gentle introduction to **argparse**, the recommended command-line parsing module in the Python standard library.

Note

There are two other modules that fulfill the same task, namely **getopt** (an equivalent for **getopt()** from the C language) and the deprecated **optparse**. Note also that **argparse** is based on **optparse**, and therefore very similar in terms of usage.

Concepts

Let's show the sort of functionality that we are going to explore in this introductory tutorial by making use of the **ls** command:

```
$ ls
cpython  devguide  prog.py  pypy  rm-unused-function.pat
$ ls pypy
ctypes_configure  demo  dotviewer  include  lib_pypy  li
$ ls -l
total 20
drwxr-xr-x 19 wena wena 4096 Feb 18 18:51 cpython
drwxr-xr-x  4 wena wena 4096 Feb  8 12:04 devguide
-rwxr-xr-x  1 wena wena  535 Feb 19 00:05 prog.py
drwxr-xr-x 14 wena wena 4096 Feb  7 00:59 pypy
-rw-r--r--  1 wena wena  741 Feb 18 01:01 rm-unused-func
$ ls --help
Usage: ls [OPTION]... [FILE]...
```

```
List information about the FILEs (the current directory
Sort entries alphabetically if none of -cftuvSUX nor --s
...
```

A few concepts we can learn from the four commands:

- The **ls** command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, `pypy`. What we did is specify what is known as a positional argument. It's named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like **cp**, whose most basic usage is `cp SRC DEST`. The first position is *what you want copied,* and the second position is *where you want it copied to*.
- Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.
- That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.

The basics

Let us start with a very simple example which does (almost) nothing:

```
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h]
```

```
options:
  -h, --help  show this help message and exit
$ python3 prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
$ python3 prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the **`argparse`** module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.

Introducing Positional arguments

An example:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```
$ python3 prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required: ec
$ python3 prog.py --help
usage: prog.py [-h] echo
```

```
positional arguments:
  echo

options:
  -h, --help  show this help message and exit
$ python3 prog.py foo
foo
```

Here is what's happening:

- We've added the **`add_argument()`** method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The **`parse_args()`** method actually returns some data from the options specified, in this case, `echo`.
- The variable is some form of 'magic' that **`argparse`** performs for free (i.e. no need to specify which variable that value is stored in). You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don't know what it does, other than by guessing or by reading the source code. So, let's make it a bit more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you us
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python3 prog.py -h
usage: prog.py [-h] echo
```

```
positional arguments:
  echo        echo the string you use here

options:
  -h, --help  show this help message and exit
```

Now, how about doing something even more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 5, in <module>
    print(args.square**2)
TypeError: unsupported operand type(s) for ** or pow():
```

That didn't go so well. That's because **argparse** treats the options we give it as strings, unless we tell it otherwise. So, let's tell **argparse** to treat that input as an integer:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of
                    type=int)
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value: 'fou
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.

Introducing Optional arguments

So far we have been playing with positional arguments. Let us have a look on how to add optional ones:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output
args = parser.parse_args()
if args.verbosity:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbosity 1
verbosity turned on
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]

options:
  -h, --help            show this help message and exit
  --verbosity VERBOSITY
                        increase output verbosity
$ python3 prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argum
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case **`args.verbosity`**, is given `None` as a value, which is

the reason it fails the truth test of the `if` statement.
- The help message is a bit different.
- When using the `--verbosity` option, one must also specify some value, any value.

The above example accepts arbitrary integer values for `--verbosity`, but for our simple program, only two values are actually useful, `True` or `False`. Let's modify the code accordingly:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output v
                    action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbose
verbosity turned on
$ python3 prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python3 prog.py --help
usage: prog.py [-h] [--verbose]

options:
  -h, --help  show this help message and exit
  --verbose   increase output verbosity
```

Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value `"store_true"`. This means that, if the option is specified, assign the value `True` to **`args.verbose`**. Not specifying it implies `False`.
- It complains when you specify a value, in true spirit of what

flags actually are.
- Notice the different help text.

Short options

If you are familiar with command line usage, you will notice that I haven't yet touched on the topic of short versions of the options. It's quite simple:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase ou
                    action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And here goes:

```
$ python3 prog.py -v
verbosity turned on
$ python3 prog.py --help
usage: prog.py [-h] [-v]

options:
  -h, --help     show this help message and exit
  -v, --verbose  increase output verbosity
```

Note that the new ability is also reflected in the help text.

Combining Positional and Optional arguments

Our program keeps growing in complexity:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
```

```
parser.add_argument("-v", "--verbose", action="store_tru
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbose:
    print(f"the square of {args.square} equals {answer}"
else:
    print(answer)
```

And now the output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required: sq
$ python3 prog.py 4
16
$ python3 prog.py 4 --verbose
the square of 4 equals 16
$ python3 prog.py --verbose 4
the square of 4 equals 16
```

- We've brought back a positional argument, hence the complaint.
- Note that the order does not matter.

How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
parser.add_argument("-v", "--verbosity", type=int,
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}"
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")
```

```
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one ar
$ python3 prog.py 4 -v 1
4^2 == 16
$ python3 prog.py 4 -v 2
the square of 4 equals 16
$ python3 prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let's fix it by restricting the values the `--verbosity` option can accept:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
parser.add_argument("-v", "--verbosity", type=int, choic
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}"
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
```

```
prog.py: error: argument -v/--verbosity: invalid choice:
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square

positional arguments:
  square                display a square of a given numb

options:
  -h, --help            show this help message and exit
  -v {0,1,2}, --verbosity {0,1,2}
                        increase output verbosity
```

Note that the change also reflects both in the error message as well as the help string.

Now, let's use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display the square of a given
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print(f"the square of {args.square} equals {answer}"
elif args.verbosity == 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

We have introduced another action, "count", to count the number of occurrences of specific options.

```
$ python3 prog.py 4
16
```

```
$ python3 prog.py 4 -v
4^2 == 16
$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python3 prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v] square

positional arguments:
  square           display a square of a given number

options:
  -h, --help       show this help message and exit
  -v, --verbosity  increase output verbosity
$ python3 prog.py 4 -vvv
16
```

- Yes, it's now more of a flag (similar to `action="store_true"`) in the previous version of our script. That should explain the complaint.
- It also behaves similar to "store_true" action.
- Now here's a demonstration of what the "count" action gives. You've probably seen this sort of usage before.
- And if you don't specify the `-v` flag, that flag is considered to have `None` value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn't very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the `help` keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```
import argparse
```

```
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2

# bugfix: replace == with >=
if args.verbosity >= 2:
    print(f"the square of {args.square} equals {answer}"
elif args.verbosity >= 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

And this is what it gives:

```
$ python3 prog.py 4 -vvv
the square of 4 equals 16
$ python3 prog.py 4 -vvvv
the square of 4 equals 16
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 11, in <module>
    if args.verbosity >= 2:
TypeError: '>=' not supported between instances of 'None
```

- First output went well, and fixes the bug we had before. That is, we want any value >= 2 to be as verbose as possible.
- Third output not so good.

Let's fix that bug:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given nu
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
```

```
args = parser.parse_args()
answer = args.square**2
if args.verbosity >= 2:
    print(f"the square of {args.square} equals {answer}"
elif args.verbosity >= 1:
    print(f"{args.square}^2 == {answer}")
else:
    print(answer)
```

We've just introduced yet another keyword, `default`. We've set it to `0` in order to make it comparable to the other int values. Remember that by default, if an optional argument isn't specified, it gets the `None` value, and that cannot be compared to an int value (hence the **`TypeError`** exception).

And:

```
$ python3 prog.py 4
16
```

You can go quite far just with what we've learned so far, and we have only scratched the surface. The **`argparse`** module is very powerful, and we'll explore a bit more of it before we end this tutorial.

Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print(f"{args.x} to the power {args.y} equals {answe
```

```
elif args.verbosity >= 1:
    print(f"{args.x}^{args.y} == {answer}")
else:
    print(answer)
```

Output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required: x,
$ python3 prog.py -h
usage: prog.py [-h] [-v] x y

positional arguments:
  x                 the base
  y                 the exponent

options:
  -h, --help        show this help message and exit
  -v, --verbosity
$ python3 prog.py 4 2 -v
4^2 == 16
```

Notice that so far we've been using verbosity level to *change* the text that gets displayed. The following example instead uses verbosity level to display *more* text instead:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print(f"Running '{__file__}'")
if args.verbosity >= 1:
    print(f"{args.x}^{args.y} == ", end="")
print(answer)
```

Output:

```
$ python3 prog.py 4 2
16
$ python3 prog.py 4 2 -v
4^2 == 16
$ python3 prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

Conflicting options

So far, we have been working with two methods of an **`argparse.ArgumentParser`** instance. Let's introduce a third one, **`add_mutually_exclusive_group()`**. It allows for us to specify options that conflict with each other. Let's also change the rest of the program so that the new functionality makes more sense: we'll introduce the `--quiet` option, which will be the opposite of the `--verbose` one:

```
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print(f"{args.x} to the power {args.y} equals {answe
else:
    print(f"{args.x}^{args.y} == {answer}")
```

Our program is now simpler, and we've lost some functionality for

the sake of demonstration. Anyways, here's the output:

```
$ python3 prog.py 4 2
4^2 == 16
$ python3 prog.py 4 2 -q
16
$ python3 prog.py 4 2 -v
4 to the power 2 equals 16
$ python3 prog.py 4 2 -vq
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with ar
$ python3 prog.py 4 2 -v --quiet
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with ar
```

That should be easy to follow. I've added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don't know:

```
import argparse

parser = argparse.ArgumentParser(description="calculate
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print(f"{args.x} to the power {args.y} equals {answe
else:
    print(f"{args.x}^{args.y} == {answer}")
```

Note that slight difference in the usage text. Note the `[-v | -q]`, which tells us that we can either use `-v` or `-q`, but not both at the same time:

```
$ python3 prog.py --help
usage: prog.py [-h] [-v | -q] x y

calculate X to the power of Y

positional arguments:
  x              the base
  y              the exponent

options:
  -h, --help     show this help message and exit
  -v, --verbose
  -q, --quiet
```

Conclusion

The **`argparse`** module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.

An introduction to the ipaddress module

author
Peter Moody
author
Nick Coghlan

Overview

This document aims to provide a gentle introduction to the `ipaddress` module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how `ipaddress` represents IP network addressing concepts.

Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol (IP) is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

IP Host Addresses

Addresses, often referred to as "host addresses" are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the **`ipaddress.ip_address()`** factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:

```
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(42540766411282592856903984951653826560)
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```
>>> ipaddress.ip_address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv4Address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv6Address(1)
IPv6Address('::1')
```

Defining Networks

Host addresses are usually grouped together into IP networks, so

ipaddress provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in **ValueError** being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
   ...
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:

```
>>> ipaddress.ip_network(3221225984)
IPv4Network('192.0.2.0/32')
>>> ipaddress.ip_network(42540766411282592856903984951653826560)
IPv6Network('2001:db8::/128')
```

As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for "the host `192.0.2.1` on the network `192.0.2.0/24`", Accordingly, **`ipaddress`** provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn't constrained to being a network address.

```
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')
>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.

Inspecting Address/Network/Interface Objects

You've gone to the trouble of creating an IPv(4|6)(Address|Network|Interface) object, so you probably want to get information about it. **`ipaddress`** tries to make doing this easy and intuitive.

Extracting the IP version:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.num_addresses
4294967296
```

Iterating through the “usable” addresses on a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...     print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network

prefix) or the hostmask (any bits that are not part of the netmask):

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
IPv6Address('ffff:ffff:ffff:ffff:ffff:ffff::')
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
>>> net6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0000/96'
>>> net6.compressed
'2001:db8::/96'
```

While IPv4 doesn't support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.

Networks as lists of Addresses

It's sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
```

```
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```

Comparisons

`ipaddress` provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_adc
True
```

A **`TypeError`** exception is raised if you try to compare objects of different versions or different types.

Using IP Addresses with other modules

Other modules that use IP addresses (such as **`socket`**) usually won't accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
```

```
>>> int(addr4)
3221225985
```

Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as **`ValueError`** with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it's necessary to know whether the value is *supposed* to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the **`ValueError`** subclasses **`ipaddress.AddressValueError`** and **`ipaddress.NetmaskValueError`** to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
  ...
ValueError: '192.168.0.256' does not appear to be an IPv
>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
  ...
ipaddress.AddressValueError: Octet 256 (> 255) not permi

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
  ...
ValueError: '192.168.0.1/64' does not appear to be an IP
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
  ...
```

```
ipaddress.NetmaskValueError: '64' is not a valid netmask
```

However, both of the module specific exceptions have **`ValueError`** as their parent class, so if you're not concerned with the particular type of error, you can still write code like the following:

```
try:
    network = ipaddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', addres
```

Argument Clinic How-To

author

Larry Hastings

Abstract

Argument Clinic is a preprocessor for CPython C files. Its purpose is to automate all the boilerplate involved with writing argument parsing code for “builtins”. This document shows you how to convert your first C function to work with Argument Clinic, and then introduces some advanced topics on Argument Clinic usage.

Currently Argument Clinic is considered internal-only for CPython. Its use is not supported for files outside CPython, and no guarantees are made regarding backwards compatibility for future versions. In other words: if you maintain an external C extension for CPython, you’re welcome to experiment with Argument Clinic in your own code. But the version of Argument Clinic that ships with the next version of CPython *could* be totally incompatible and break all your code.

The Goals Of Argument Clinic

Argument Clinic’s primary goal is to take over responsibility for all argument parsing code inside CPython. This means that, when you convert a function to work with Argument Clinic, that function should no longer do any of its own argument parsing—the code generated by Argument Clinic should be a “black box” to you, where CPython calls in at the top, and your code gets called at the bottom, with `PyObject *args` (and maybe `PyObject *kwargs`) magically converted into the C variables and types you need.

In order for Argument Clinic to accomplish its primary goal, it must be easy to use. Currently, working with CPython's argument parsing library is a chore, requiring maintaining redundant information in a surprising number of places. When you use Argument Clinic, you don't have to repeat yourself.

Obviously, no one would want to use Argument Clinic unless it's solving their problem—and without creating new problems of its own. So it's paramount that Argument Clinic generate correct code. It'd be nice if the code was faster, too, but at the very least it should not introduce a major speed regression. (Eventually Argument Clinic *should* make a major speedup possible—we could rewrite its code generator to produce tailor-made argument parsing code, rather than calling the general-purpose CPython argument parsing library. That would make for the fastest argument parsing possible!)

Additionally, Argument Clinic must be flexible enough to work with any approach to argument parsing. Python has some functions with some very strange parsing behaviors; Argument Clinic's goal is to support all of them.

Finally, the original motivation for Argument Clinic was to provide introspection "signatures" for CPython builtins. It used to be, the introspection query functions would throw an exception if you passed in a builtin. With Argument Clinic, that's a thing of the past!

One idea you should keep in mind, as you work with Argument Clinic: the more information you give it, the better job it'll be able to do. Argument Clinic is admittedly relatively simple right now. But as it evolves it will get more sophisticated, and it should be able to do many interesting and smart things with all the information you give it.

Basic Concepts And Usage

Argument Clinic ships with CPython; you'll find it in `Tools/clinic/clinic.py`. If you run that script, specifying a C file as an argument:

```
$ python3 Tools/clinic/clinic.py foo.c
```

Argument Clinic will scan over the file looking for lines that look exactly like this:

```
/*[clinic input]
```

When it finds one, it reads everything up to a line that looks exactly like this:

```
[clinic start generated code]*/
```

Everything in between these two lines is input for Argument Clinic. All of these lines, including the beginning and ending comment lines, are collectively called an Argument Clinic "block".

When Argument Clinic parses one of these blocks, it generates output. This output is rewritten into the C file immediately after the block, followed by a comment containing a checksum. The Argument Clinic block now looks like this:

```
/*[clinic input]
... clinic input goes here ...
[clinic start generated code]*/
... clinic output goes here ...
/*[clinic end generated code: checksum=...]*/
```

If you run Argument Clinic on the same file a second time, Argument Clinic will discard the old output and write out the new output with a fresh checksum line. However, if the input hasn't changed, the output won't change either.

You should never modify the output portion of an Argument Clinic block. Instead, change the input until it produces the output you want. (That's the purpose of the checksum—to detect if someone changed the output, as these edits would be lost the next time Argument Clinic writes out fresh output.)

For the sake of clarity, here's the terminology we'll use with Argument Clinic:

- The first line of the comment (`/*[clinic input]`) is the *start line*.

- The last line of the initial comment (`[clinic start generated code]*/`) is the *end line*.
- The last line (`/*[clinic end generated code: checksum=...]*/`) is the *checksum line*.
- In between the start line and the end line is the *input*.
- In between the end line and the checksum line is the *output*.
- All the text collectively, from the start line to the checksum line inclusively, is the *block*. (A block that hasn't been successfully processed by Argument Clinic yet doesn't have output or a checksum line, but it's still considered a block.)

Converting Your First Function

The best way to get a sense of how Argument Clinic works is to convert a function to work with it. Here, then, are the bare minimum steps you'd need to follow to convert a function to work with Argument Clinic. Note that for code you plan to check in to CPython, you really should take the conversion farther, using some of the advanced concepts you'll see later on in the document (like "return converters" and "self converters"). But we'll keep it simple for this walkthrough so you can learn.

Let's dive in!

1. Make sure you're working with a freshly updated checkout of the CPython trunk.

2. Find a Python builtin that calls either **`PyArg_ParseTuple()`** or **`PyArg_ParseTupleAndKeywords()`**, and hasn't been converted to work with Argument Clinic yet. For my example I'm using `_pickle.Pickler.dump()`.

3. If the call to the `PyArg_Parse` function uses any of the following format units:

   ```
   O&
   O!
   es
   es#
   ```

```
et
et#
```

or if it has multiple calls to **`PyArg_ParseTuple()`**, you should choose a different function. Argument Clinic *does* support all of these scenarios. But these are advanced topics—let's do something simpler for your first function.

Also, if the function has multiple calls to **`PyArg_ParseTuple()`** or **`PyArg_ParseTupleAndKeywords()`** where it supports different types for the same argument, or if the function uses something besides PyArg_Parse functions to parse its arguments, it probably isn't suitable for conversion to Argument Clinic. Argument Clinic doesn't support generic functions or polymorphic parameters.

4. Add the following boilerplate above the function, creating our block:

```
/*[clinic input]
[clinic start generated code]*/
```

5. Cut the docstring and paste it in between the `[clinic]` lines, removing all the junk that makes it a properly quoted C string. When you're done you should have just the text, based at the left margin, with no line wider than 80 characters. (Argument Clinic will preserve indents inside the docstring.)

   If the old docstring had a first line that looked like a function signature, throw that line away. (The docstring doesn't need it anymore—when you use `help()` on your builtin in the future, the first line will be built automatically based on the function's signature.)

   Sample:

```
/*[clinic input]
Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

6. If your docstring doesn't have a "summary" line, Argument Clinic will complain. So let's make sure it has one. The "summary" line should be a paragraph consisting of a single 80-column line at the beginning of the docstring.

   (Our example docstring consists solely of a summary line, so the sample code doesn't have to change for this step.)

7. Above the docstring, enter the name of the function, followed by a blank line. This should be the Python name of the function, and should be the full dotted path to the function—it should start with the name of the module, include any sub-modules, and if the function is a method on a class it should include the class name too.

   Sample:

```
/*[clinic input]
_pickle.Pickler.dump

Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

8. If this is the first time that module or class has been used with Argument Clinic in this C file, you must declare the module and/or class. Proper Argument Clinic hygiene prefers declaring these in a separate block somewhere near the top of the C file, in the same way that include files and statics go at the top. (In our sample code we'll just show the two blocks next to each other.)

   The name of the class and module should be the same as the one seen by Python. Check the name defined in the **`PyModuleDef`** or **`PyTypeObject`** as appropriate.

   When you declare a class, you must also specify two aspects of its type in C: the type declaration you'd use for a pointer to an instance of this class, and a pointer to the **`PyTypeObject`** for this class.

   Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

9. Declare each of the parameters to the function. Each parameter should get its own line. All the parameter lines should be indented from the function name and the docstring.

   The general form of these parameter lines is as follows:

   ```
   name_of_parameter: converter
   ```

   If the parameter has a default value, add that after the converter:

   ```
   name_of_parameter: converter = default_value
   ```

   Argument Clinic's support for "default values" is quite sophisticated; please see the section below on default values for more information.

   Add a blank line below the parameters.

   What's a "converter"? It establishes both the type of the variable used in C, and the method to convert the Python value into a C value at runtime. For now you're going to use what's called a "legacy converter"—a convenience syntax intended to make porting old code into Argument Clinic easier.

   For each parameter, copy the "format unit" for that parameter from the `PyArg_Parse()` format argument and specify *that* as its converter, as a quoted string. ("format unit" is the formal name for the one-to-three character substring of

the `format` parameter that tells the argument parsing function what the type of the variable is and how to convert it. For more on format units please see Parsing arguments and building values.)

For multicharacter format units like `z#`, use the entire two-or-three character string.

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

    obj: 'O'

Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

10. If your function has `|` in the format string, meaning some parameters have default values, you can ignore it. Argument Clinic infers which parameters are optional based on whether or not they have default values.

    If your function has `$` in the format string, meaning it takes keyword-only arguments, specify `*` on a line by itself before the first keyword-only argument, indented the same as the parameter lines.

    (`_pickle.Pickler.dump` has neither, so our sample is unchanged.)

11. If the existing C function calls **`PyArg_ParseTuple()`** (as opposed to **`PyArg_ParseTupleAndKeywords()`**), then all its arguments are positional-only.

    To mark all parameters as positional-only in Argument Clinic,

add a `/` on a line by itself after the last parameter, indented the same as the parameter lines.

Currently this is all-or-nothing; either all parameters are positional-only, or none of them are. (In the future Argument Clinic may relax this restriction.)

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

    obj: 'O'
    /

Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

12. It's helpful to write a per-parameter docstring for each parameter. But per-parameter docstrings are optional; you can skip this step if you prefer.

    Here's how to add a per-parameter docstring. The first line of the per-parameter docstring must be indented further than the parameter definition. The left margin of this first line establishes the left margin for the whole per-parameter docstring; all the text you write will be outdented by this amount. You can write as much text as you like, across multiple lines if you wish.

    Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
```

```
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

    obj: 'O'
        The object to be pickled.
    /

Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

13. Save and close the file, then run `Tools/clinic/clinic.py` on it. With luck everything worked—your block now has output, and a `.c.h` file has been generated! Reopen the file in your text editor to see:

```
/*[clinic input]
_pickle.Pickler.dump

    obj: 'O'
        The object to be pickled.
    /

Write a pickled representation of obj to the open f
[clinic start generated code]*/

static PyObject *
_pickle_Pickler_dump(PicklerObject *self, PyObject
/*[clinic end generated code: output=87ecad1261e02a
```

Obviously, if Argument Clinic didn't produce any output, it's because it found an error in your input. Keep fixing your errors and retrying until Argument Clinic processes your file without complaint.

For readability, most of the glue code has been generated to a `.c.h` file. You'll need to include that in your original `.c` file, typically right after the clinic module block:

```
#include "clinic/_pickle.c.h"
```

14. Double-check that the argument-parsing code Argument Clinic generated looks basically the same as the existing code.

    First, ensure both places use the same argument-parsing function. The existing code must call either **`PyArg_ParseTuple()`** or **`PyArg_ParseTupleAndKeywords()`**; ensure that the code generated by Argument Clinic calls the *exact* same function.

    Second, the format string passed in to **`PyArg_ParseTuple()`** or **`PyArg_ParseTupleAndKeywords()`** should be *exactly* the same as the hand-written one in the existing function, up to the colon or semi-colon.

    (Argument Clinic always generates its format strings with a `:` followed by the name of the function. If the existing code's format string ends with `;`, to provide usage help, this change is harmless—don't worry about it.)

    Third, for parameters whose format units require two arguments (like a length variable, or an encoding string, or a pointer to a conversion function), ensure that the second argument is *exactly* the same between the two invocations.

    Fourth, inside the output portion of the block you'll find a preprocessor macro defining the appropriate static **`PyMethodDef`** structure for this builtin:

    ```
    #define __PICKLE_PICKLER_DUMP_METHODDEF    \
    {"dump", (PyCFunction)__pickle_Pickler_dump, METH_O
    ```

    This static structure should be *exactly* the same as the existing static **`PyMethodDef`** structure for this builtin.

    If any of these items differ in *any way*, adjust your Argument Clinic function specification and rerun `Tools/clinic/clinic.py` until they *are* the same.

15. Notice that the last line of its output is the declaration of your "impl" function. This is where the builtin's implementation goes. Delete the existing prototype of the function you're modifying, but leave the opening curly brace. Now delete its argument parsing code and the declarations of all the variables it dumps the arguments into. Notice how the Python arguments are now arguments to this impl function; if the implementation used different names for these variables, fix it.

    Let's reiterate, just because it's kind of weird. Your code should now look like this:

    ```
    static return_type
    your_function_impl(...)
    /*[clinic end generated code: checksum=...]*/
    {
    ...
    ```

    Argument Clinic generated the checksum line and the function prototype just above it. You should write the opening (and closing) curly braces for the function, and the implementation inside.

    Sample:

    ```
    /*[clinic input]
    module _pickle
    class _pickle.Pickler "PicklerObject *" "&Pickler_T
    [clinic start generated code]*/
    /*[clinic end generated code: checksum=da39a3ee5e6b

    /*[clinic input]
    _pickle.Pickler.dump

        obj: 'O'
            The object to be pickled.
        /

    Write a pickled representation of obj to the open f
    ```

```
[clinic start generated code]*/

PyDoc_STRVAR(__pickle_Pickler_dump__doc__,
"Write a pickled representation of obj to the open
"\n"
...
static PyObject *
_pickle_Pickler_dump_impl(PicklerObject *self, PyOb
/*[clinic end generated code: checksum=3bd30745bf20
{
    /* Check whether the Pickler was initialized co
       Developers often forget to call __init__() i
       would trigger a segfault without this check.
    if (self->write == NULL) {
        PyErr_Format(PicklingError,
                     "Pickler.__init__() was not ca
                     Py_TYPE(self)->tp_name);
        return NULL;
    }

    if (_Pickler_ClearBuffer(self) < 0)
        return NULL;

    ...
```

16. Remember the macro with the **PyMethodDef** structure for this function? Find the existing **PyMethodDef** structure for this function and replace it with a reference to the macro. (If the builtin is at module scope, this will probably be very near the end of the file; if the builtin is a class method, this will probably be below but relatively near to the implementation.)

    Note that the body of the macro contains a trailing comma. So when you replace the existing static **PyMethodDef** structure with the macro, *don't* add a comma to the end.

    Sample:

```
static struct PyMethodDef Pickler_methods[] = {
    __PICKLE_PICKLER_DUMP_METHODDEF
```

```
    __PICKLE_PICKLER_CLEAR_MEMO_METHODDEF
    {NULL, NULL}                /* sentinel */
};
```

17. Compile, then run the relevant portions of the regression-test suite. This change should not introduce any new compile-time warnings or errors, and there should be no externally visible change to Python's behavior.

    Well, except for one difference: `inspect.signature()` run on your function should now provide a valid signature!

    Congratulations, you've ported your first function to work with Argument Clinic!

Advanced Topics

Now that you've had some experience working with Argument Clinic, it's time for some advanced topics.

Symbolic default values

The default value you provide for a parameter can't be any arbitrary expression. Currently the following are explicitly supported:

- Numeric constants (integer and float)
- String constants
- `True`, `False`, and `None`
- Simple symbolic constants like `sys.maxsize`, which must start with the name of the module

(In the future, this may need to get even more elaborate, to allow full expressions like `CONSTANT - 1`.)

Renaming the C functions and variables generated by Argument Clinic

Argument Clinic automatically names the functions it generates for you. Occasionally this may cause a problem, if the generated name

collides with the name of an existing C function. There's an easy solution: override the names used for the C functions. Just add the keyword `"as"` to your function declaration line, followed by the function name you wish to use. Argument Clinic will use that function name for the base (generated) function, then add `"_impl"` to the end and use that for the name of the impl function.

For example, if we wanted to rename the C function names generated for `pickle.Pickler.dump`, it'd look like this:

```
/*[clinic input]
pickle.Pickler.dump as pickler_dumper

...
```

The base function would now be named `pickler_dumper()`, and the impl function would now be named `pickler_dumper_impl()`.

Similarly, you may have a problem where you want to give a parameter a specific Python name, but that name may be inconvenient in C. Argument Clinic allows you to give a parameter different names in Python and in C, using the same `"as"` syntax:

```
/*[clinic input]
pickle.Pickler.dump

    obj: object
    file as file_obj: object
    protocol: object = NULL
    *
    fix_imports: bool = True
```

Here, the name used in Python (in the signature and the `keywords` array) would be `file`, but the C variable would be named `file_obj`.

You can use this to rename the `self` parameter too!

Converting functions using PyArg_UnpackTuple

To convert a function parsing its arguments with **`PyArg_UnpackTuple()`**, simply write out all the arguments, specifying each as an `object`. You may specify the `type` argument to cast the type as appropriate. All arguments should be marked positional-only (add a `/` on a line by itself after the last argument).

Currently the generated code will use **`PyArg_ParseTuple()`**, but this will change soon.

Optional Groups

Some legacy functions have a tricky approach to parsing their arguments: they count the number of positional arguments, then use a `switch` statement to call one of several different **`PyArg_ParseTuple()`** calls depending on how many positional arguments there are. (These functions cannot accept keyword-only arguments.) This approach was used to simulate optional arguments back before **`PyArg_ParseTupleAndKeywords()`** was created.

While functions using this approach can often be converted to use **`PyArg_ParseTupleAndKeywords()`**, optional arguments, and default values, it's not always possible. Some of these legacy functions have behaviors **`PyArg_ParseTupleAndKeywords()`** doesn't directly support. The most obvious example is the builtin function `range()`, which has an optional argument on the *left* side of its required argument! Another example is `curses.window.addch()`, which has a group of two arguments that must always be specified together. (The arguments are called `x` and `y`; if you call the function passing in `x`, you must also pass in `y`—and if you don't pass in `x` you may not pass in `y` either.)

In any case, the goal of Argument Clinic is to support argument parsing for all existing CPython builtins without changing their semantics. Therefore Argument Clinic supports this alternate approach to parsing, using what are called *optional groups*. Optional groups are groups of arguments that must all be passed in together. They can be to the left or the right of the required arguments. They can *only* be used with positional-only parameters.

Note

Optional groups are *only* intended for use when converting functions that make multiple calls to `PyArg_ParseTuple()`! Functions that use *any* other approach for parsing arguments should *almost never* be converted to Argument Clinic using optional groups. Functions using optional groups currently cannot have accurate signatures in Python, because Python just doesn't understand the concept. Please avoid using optional groups wherever possible.

To specify an optional group, add a `[` on a line by itself before the parameters you wish to group together, and a `]` on a line by itself after these parameters. As an example, here's how `curses.window.addch` uses optional groups to make the first two parameters and the last parameter optional:

```
/*[clinic input]

curses.window.addch

    [
    x: int
      X-coordinate.
    y: int
      Y-coordinate.
    ]

    ch: object
      Character to add.

    [
    attr: long
      Attributes for the character.
    ]
    /

...
```

Notes:

- For every optional group, one additional parameter will be passed into the impl function representing the group. The parameter will be an int named `group_{direction}_{number}`, where `{direction}` is either `right` or `left` depending on whether the group is before or after the required parameters, and `{number}` is a monotonically increasing number (starting at 1) indicating how far away the group is from the required parameters. When the impl is called, this parameter will be set to zero if this group was unused, and set to non-zero if this group was used. (By used or unused, I mean whether or not the parameters received arguments in this invocation.)
- If there are no required arguments, the optional groups will behave as if they're to the right of the required arguments.
- In the case of ambiguity, the argument parsing code favors parameters on the left (before the required parameters).
- Optional groups can only contain positional-only parameters.
- Optional groups are *only* intended for legacy code. Please do not use optional groups for new code.

Using real Argument Clinic converters, instead of "legacy converters"

To save time, and to minimize how much you need to learn to achieve your first port to Argument Clinic, the walkthrough above tells you to use "legacy converters". "Legacy converters" are a convenience, designed explicitly to make porting existing code to Argument Clinic easier. And to be clear, their use is acceptable when porting code for Python 3.4.

However, in the long term we probably want all our blocks to use Argument Clinic's real syntax for converters. Why? A couple reasons:

- The proper converters are far easier to read and clearer in their intent.
- There are some format units that are unsupported as "legacy converters", because they require arguments, and the legacy

converter syntax doesn't support specifying arguments.
- In the future we may have a new argument parsing library that isn't restricted to what **`PyArg_ParseTuple()`** supports; this flexibility won't be available to parameters using legacy converters.

Therefore, if you don't mind a little extra effort, please use the normal converters instead of legacy converters.

In a nutshell, the syntax for Argument Clinic (non-legacy) converters looks like a Python function call. However, if there are no explicit arguments to the function (all functions take their default values), you may omit the parentheses. Thus `bool` and `bool()` are exactly the same converters.

All arguments to Argument Clinic converters are keyword-only. All Argument Clinic converters accept the following arguments:

`c_default`
: The default value for this parameter when defined in C. Specifically, this will be the initializer for the variable declared in the "parse function". See the section on default values for how to use this. Specified as a string.

`annotation`
: The annotation value for this parameter. Not currently supported, because **PEP 8** [https://peps.python.org/pep-0008/] mandates that the Python library may not use annotations.

In addition, some converters accept additional arguments. Here is a list of these arguments, along with their meanings:

`accept`
: A set of Python types (and possibly pseudo-types); this restricts the allowable Python argument to values of these types. (This is not a general-purpose facility; as a rule it only supports specific lists of types as shown

in the legacy converter table.)

To accept `None`, add `NoneType` to this set.

`bitwise`

Only supported for unsigned integers. The native integer value of this Python argument will be written to the parameter without any range checking, even for negative values.

`converter`

Only supported by the `object` converter. Specifies the name of a C "converter function" to use to convert this object to a native type.

`encoding`

Only supported for strings. Specifies the encoding to use when converting this string from a Python str (Unicode) value into a C `char *` value.

`subclass_of`

Only supported for the `object` converter. Requires that the Python value be a subclass of a Python type, as expressed in C.

`type`

Only supported for the `object` and `self` converters. Specifies the C type that will be used to declare the variable. Default value is `"PyObject *"`.

`zeroes`

Only supported for strings. If true, embedded NUL bytes (`'\\0'`) are permitted inside the value. The length of the string will be passed in to the impl function, just after the string parameter, as a parameter named `<parameter_name>_length`.

Please note, not every possible combination of arguments will work. Usually these arguments are implemented by specific `PyArg_ParseTuple` *format units*, with specific behavior. For example, currently you cannot call `unsigned_short` without also specifying `bitwise=True`. Although it's perfectly reasonable to think this would work, these semantics don't map to any existing format unit. So Argument Clinic doesn't support it. (Or, at least, not yet.)

Below is a table showing the mapping of legacy converters into real Argument Clinic converters. On the left is the legacy converter, on the right is the text you'd replace it with.

`B`	`unsigned_char(bitwise=True)`
`b`	`unsigned_char`
`c`	`char`
`C`	`int(accept={str})`
`d`	`double`
`D`	`Py_complex`
`es`	`str(encoding='name_of_encoding')`
`es#`	`str(encoding='name_of_encoding', zeroes=True)`
`et`	`str(encoding='name_of_encoding', accept={bytes, bytearray, str})`
`et#`	`str(encoding='name_of_encoding', accept={bytes, bytearray, str}, zeroes=True)`
`f`	`float`
`h`	`short`
`H`	`unsigned_short(bitwise=True)`
`i`	`int`
`I`	`unsigned_int(bitwise=True)`
`k`	`unsigned_long(bitwise=True)`
`K`	`unsigned_long_long(bitwise=True)`
`l`	`long`
`L`	`long long`
`n`	`Py_ssize_t`
`O`	`object`
`O!`	`object(subclass_of='&PySomething_Type')`
`O&`	`object(converter='name_of_c_function')`
`p`	`bool`
`S`	`PyBytesObject`

s
s#
Py*
u
PyU
PyU#
Pw*
PY
sy
sy#
Py*
PZ
PZ#
sz
sz#
Pz*

As an example, here's our sample `pickle.Pickler.dump` using the proper converter:

```
/*[clinic input]
pickle.Pickler.dump

    obj: object
        The object to be pickled.
    /

Write a pickled representation of obj to the open file.
[clinic start generated code]*/
```

One advantage of real converters is that they're more flexible than legacy converters. For example, the `unsigned_int` converter (and all the `unsigned_` converters) can be specified without `bitwise=True`. Their default behavior performs range checking on the value, and they won't accept negative numbers. You just can't do that with a legacy converter!

Argument Clinic will show you all the converters it has available. For each converter it'll show you all the parameters it accepts, along with the default value for each parameter. Just run `Tools/`

`clinic/clinic.py --converters` to see the full list.

Py_buffer

When using the `Py_buffer` converter (or the `'s*'`, `'w*'`, `'*y'`, or `'z*'` legacy converters), you *must* not call **`PyBuffer_Release()`** on the provided buffer. Argument Clinic generates code that does it for you (in the parsing function).

Advanced converters

Remember those format units you skipped for your first time because they were advanced? Here's how to handle those too.

The trick is, all those format units take arguments—either conversion functions, or types, or strings specifying an encoding. (But "legacy converters" don't support arguments. That's why we skipped them for your first function.) The argument you specified to the format unit is now an argument to the converter; this argument is either `converter` (for `O&`), `subclass_of` (for `O!`), or `encoding` (for all the format units that start with `e`).

When using `subclass_of`, you may also want to use the other custom argument for `object(): type`, which lets you set the type actually used for the parameter. For example, if you want to ensure that the object is a subclass of `PyUnicode_Type`, you probably want to use the converter `object(type='PyUnicodeObject *', subclass_of='&PyUnicode_Type')`.

One possible problem with using Argument Clinic: it takes away some possible flexibility for the format units starting with `e`. When writing a `PyArg_Parse` call by hand, you could theoretically decide at runtime what encoding string to pass in to **`PyArg_ParseTuple()`**. But now this string must be hard-coded at Argument-Clinic-preprocessing-time. This limitation is deliberate; it made supporting this format unit much easier, and may allow for future optimizations. This restriction doesn't seem unreasonable; CPython itself always passes in static hard-coded encoding strings for parameters whose format units start with `e`.

Parameter default values

Default values for parameters can be any of a number of values. At their simplest, they can be string, int, or float literals:

```
foo: str = "abc"
bar: int = 123
bat: float = 45.6
```

They can also use any of Python's built-in constants:

```
yep:  bool = True
nope: bool = False
nada: object = None
```

There's also special support for a default value of `NULL`, and for simple expressions, documented in the following sections.

The `NULL` default value

For string and object parameters, you can set them to `None` to indicate that there's no default. However, that means the C variable will be initialized to `Py_None`. For convenience's sakes, there's a special value called `NULL` for just this reason: from Python's perspective it behaves like a default value of `None`, but the C variable is initialized with `NULL`.

Expressions specified as default values

The default value for a parameter can be more than just a literal value. It can be an entire expression, using math operators and looking up attributes on objects. However, this support isn't exactly simple, because of some non-obvious semantics.

Consider the following example:

```
foo: Py_ssize_t = sys.maxsize - 1
```

`sys.maxsize` can have different values on different platforms. Therefore Argument Clinic can't simply evaluate that expression

locally and hard-code it in C. So it stores the default in such a way that it will get evaluated at runtime, when the user asks for the function's signature.

What namespace is available when the expression is evaluated? It's evaluated in the context of the module the builtin came from. So, if your module has an attribute called "`max_widgets`", you may simply use it:

```
foo: Py_ssize_t = max_widgets
```

If the symbol isn't found in the current module, it fails over to looking in `sys.modules`. That's how it can find `sys.maxsize` for example. (Since you don't know in advance what modules the user will load into their interpreter, it's best to restrict yourself to modules that are preloaded by Python itself.)

Evaluating default values only at runtime means Argument Clinic can't compute the correct equivalent C default value. So you need to tell it explicitly. When you use an expression, you must also specify the equivalent expression in C, using the `c_default` parameter to the converter:

```
foo: Py_ssize_t(c_default="PY_SSIZE_T_MAX - 1") = sys.ma
```

Another complication: Argument Clinic can't know in advance whether or not the expression you supply is valid. It parses it to make sure it looks legal, but it can't *actually* know. You must be very careful when using expressions to specify values that are guaranteed to be valid at runtime!

Finally, because expressions must be representable as static C values, there are many restrictions on legal expressions. Here's a list of Python features you're not permitted to use:

- Function calls.
- Inline if statements (`3 if foo else 5`).
- Automatic sequence unpacking (`*[1, 2, 3]`).
- List/set/dict comprehensions and generator expressions.
- Tuple/list/set/dict literals.

Using a return converter

By default the impl function Argument Clinic generates for you returns `PyObject *`. But your C function often computes some C type, then converts it into the `PyObject *` at the last moment. Argument Clinic handles converting your inputs from Python types into native C types—why not have it convert your return value from a native C type into a Python type too?

That's what a "return converter" does. It changes your impl function to return some C type, then adds code to the generated (non-impl) function to handle converting that value into the appropriate `PyObject *`.

The syntax for return converters is similar to that of parameter converters. You specify the return converter like it was a return annotation on the function itself. Return converters behave much the same as parameter converters; they take arguments, the arguments are all keyword-only, and if you're not changing any of the default arguments you can omit the parentheses.

(If you use both `"as"` *and* a return converter for your function, the `"as"` should come before the return converter.)

There's one additional complication when using return converters: how do you indicate an error has occurred? Normally, a function returns a valid (non-`NULL`) pointer for success, and `NULL` for failure. But if you use an integer return converter, all integers are valid. How can Argument Clinic detect an error? Its solution: each return converter implicitly looks for a special value that indicates an error. If you return that value, and an error has been set (`PyErr_Occurred()` returns a true value), then the generated code will propagate the error. Otherwise it will encode the value you return like normal.

Currently Argument Clinic supports only a few return converters:

```
bool
int
unsigned int
long
```

```
unsigned int
size_t
Py_ssize_t
float
double
DecodeFSDefault
```

None of these take parameters. For the first three, return -1 to indicate error. For `DecodeFSDefault`, the return type is `const char *`; return a `NULL` pointer to indicate an error.

(There's also an experimental `NoneType` converter, which lets you return `Py_None` on success or `NULL` on failure, without having to increment the reference count on `Py_None`. I'm not sure it adds enough clarity to be worth using.)

To see all the return converters Argument Clinic supports, along with their parameters (if any), just run `Tools/clinic/clinic.py --converters` for the full list.

Cloning existing functions

If you have a number of functions that look similar, you may be able to use Clinic's "clone" feature. When you clone an existing function, you reuse:

- its parameters, including
  - their names,
  - their converters, with all parameters,
  - their default values,
  - their per-parameter docstrings,
  - their *kind* (whether they're positional only, positional or keyword, or keyword only), and
- its return converter.

The only thing not copied from the original function is its docstring; the syntax allows you to specify a new docstring.

Here's the syntax for cloning a function:

```
/*[clinic input]
```

```
module.class.new_function [as c_basename] = module.class

Docstring for new_function goes here.
[clinic start generated code]*/
```

(The functions can be in different modules or classes. I wrote `module.class` in the sample just to illustrate that you must use the full path to *both* functions.)

Sorry, there's no syntax for partially cloning a function, or cloning a function then modifying it. Cloning is an all-or nothing proposition.

Also, the function you are cloning from must have been previously defined in the current file.

Calling Python code

The rest of the advanced topics require you to write Python code which lives inside your C file and modifies Argument Clinic's runtime state. This is simple: you simply define a Python block.

A Python block uses different delimiter lines than an Argument Clinic function block. It looks like this:

```
/*[python input]
# python code goes here
[python start generated code]*/
```

All the code inside the Python block is executed at the time it's parsed. All text written to stdout inside the block is redirected into the "output" after the block.

As an example, here's a Python block that adds a static integer variable to the C code:

```
/*[python input]
print('static int __ignored_unused_variable__ = 0;')
[python start generated code]*/
static int __ignored_unused_variable__ = 0;
/*[python checksum:...]*/
```

Using a “self converter”

Argument Clinic automatically adds a “self” parameter for you using a default converter. It automatically sets the `type` of this parameter to the “pointer to an instance” you specified when you declared the type. However, you can override Argument Clinic’s converter and specify one yourself. Just add your own `self` parameter as the first parameter in a block, and ensure that its converter is an instance of `self_converter` or a subclass thereof.

What’s the point? This lets you override the type of `self`, or give it a different default name.

How do you specify the custom type you want to cast `self` to? If you only have one or two functions with the same type for `self`, you can directly use Argument Clinic’s existing `self` converter, passing in the type you want to use as the `type` parameter:

```
/*[clinic input]

_pickle.Pickler.dump

  self: self(type="PicklerObject *")
  obj: object
  /

Write a pickled representation of the given object to th
[clinic start generated code]*/
```

On the other hand, if you have a lot of functions that will use the same type for `self`, it’s best to create your own converter, subclassing `self_converter` but overwriting the `type` member:

```
/*[python input]
class PicklerObject_converter(self_converter):
    type = "PicklerObject *"
[python start generated code]*/

/*[clinic input]
```

```
_pickle.Pickler.dump

  self: PicklerObject
  obj: object
  /

Write a pickled representation of the given object to th
[clinic start generated code]*/
```

Using a “defining class” converter

Argument Clinic facilitates gaining access to the defining class of a method. This is useful for heap type methods that need to fetch module level state. Use **`PyType_FromModuleAndSpec()`** to associate a new heap type with a module. You can now use **`PyType_GetModuleState()`** on the defining class to fetch the module state, for example from a module method.

Example from `Modules/zlibmodule.c`. First, `defining_class` is added to the clinic input:

```
/*[clinic input]
zlib.Compress.compress

  cls: defining_class
  data: Py_buffer
    Binary data to be compressed.
  /
```

After running the Argument Clinic tool, the following function signature is generated:

```
/*[clinic start generated code]*/
static PyObject *
zlib_Compress_compress_impl(compobject *self, PyTypeObje
                            Py_buffer *data)
/*[clinic end generated code: output=6731b3f0ff357ca6 in
```

The following code can now use `PyType_GetModuleState(cls)` to fetch the module state:

```
zlibstate *state = PyType_GetModuleState(cls);
```

Each method may only have one argument using this converter, and it must appear after `self`, or, if `self` is not used, as the first argument. The argument will be of type `PyTypeObject *`. The argument will not appear in the `__text_signature__`.

The `defining_class` converter is not compatible with `__init__` and `__new__` methods, which cannot use the `METH_METHOD` convention.

It is not possible to use `defining_class` with slot methods. In order to fetch the module state from such methods, use **`PyType_GetModuleByDef()`** to look up the module and then **`PyModule_GetState()`** to fetch the module state. Example from the `setattro` slot method in `Modules/_threadmodule.c`:

```
static int
local_setattro(localobject *self, PyObject *name, PyObje
{
    PyObject *module = PyType_GetModuleByDef(Py_TYPE(sel
    thread_module_state *state = get_thread_state(module
    ...
}
```

See also **PEP 573** [https://peps.python.org/pep-0573/].

Writing a custom converter

As we hinted at in the previous section… you can write your own converters! A converter is simply a Python class that inherits from `CConverter`. The main purpose of a custom converter is if you have a parameter using the `O&` format unit—parsing this parameter means calling a **`PyArg_ParseTuple()`** "converter function".

Your converter class should be named `*something*_converter`. If the name follows this convention, then your converter class will be automatically registered with Argument Clinic; its name will be the name of your class with the `_converter` suffix stripped off. (This is accomplished with a metaclass.)

You shouldn't subclass `CConverter.__init__`. Instead, you should write a `converter_init()` function. `converter_init()` always accepts a `self` parameter; after that, all additional parameters *must* be keyword-only. Any arguments passed in to the converter in Argument Clinic will be passed along to your `converter_init()`.

There are some additional members of `CConverter` you may wish to specify in your subclass. Here's the current list:

`type`
: The C type to use for this variable. `type` should be a Python string specifying the type, e.g. `int`. If this is a pointer type, the type string should end with `' *'`.

`default`
: The Python default value for this parameter, as a Python value. Or the magic value `unspecified` if there is no default.

`py_default`
: `default` as it should appear in Python code, as a string. Or `None` if there is no default.

`c_default`
: `default` as it should appear in C code, as a string. Or `None` if there is no default.

`c_ignored_default`
: The default value used to initialize the C variable when there is no default, but not specifying a default may result in an "uninitialized variable" warning. This can easily happen when using option groups—although properly written code will never actually use this value, the variable does get passed in to the impl, and the C compiler will complain about the "use" of the uninitialized value. This value should always be a non-empty string.

`converter`
: The name of the C converter function, as a string.

`impl_by_reference`
: A boolean value. If true, Argument Clinic will add a `&` in front of the name of the variable when passing it into the impl function.

`parse_by_reference`
: A boolean value. If true, Argument Clinic will add a `&` in front of the name of the variable when passing it into **`PyArg_ParseTuple()`**.

Here's the simplest example of a custom converter, from `Modules/zlibmodule.c`:

```
/*[python input]

class ssize_t_converter(CConverter):
    type = 'Py_ssize_t'
    converter = 'ssize_t_converter'

[python start generated code]*/
/*[python end generated code: output=da39a3ee5e6b4b0d ir
```

This block adds a converter to Argument Clinic named `ssize_t`. Parameters declared as `ssize_t` will be declared as type **`Py_ssize_t`**, and will be parsed by the `'O&'` format unit, which will call the `ssize_t_converter` converter function. `ssize_t` variables automatically support default values.

More sophisticated custom converters can insert custom C code to handle initialization and cleanup. You can see more examples of custom converters in the CPython source tree; grep the C files for the string `CConverter`.

Writing a custom return converter

Writing a custom return converter is much like writing a custom converter. Except it's somewhat simpler, because return converters are themselves much simpler.

Return converters must subclass `CReturnConverter`. There are

no examples yet of custom return converters, because they are not widely used yet. If you wish to write your own return converter, please read `Tools/clinic/clinic.py`, specifically the implementation of `CReturnConverter` and all its subclasses.

METH_O and METH_NOARGS

To convert a function using `METH_O`, make sure the function's single argument is using the `object` converter, and mark the arguments as positional-only:

```
/*[clinic input]
meth_o_sample

     argument: object
     /
[clinic start generated code]*/
```

To convert a function using `METH_NOARGS`, just don't specify any arguments.

You can still use a self converter, a return converter, and specify a `type` argument to the object converter for `METH_O`.

tp_new and tp_init functions

You can convert `tp_new` and `tp_init` functions. Just name them `__new__` or `__init__` as appropriate. Notes:

- The function name generated for `__new__` doesn't end in `__new__` like it would by default. It's just the name of the class, converted into a valid C identifier.
- No `PyMethodDef #define` is generated for these functions.
- `__init__` functions return `int`, not `PyObject *`.
- Use the docstring as the class docstring.
- Although `__new__` and `__init__` functions must always accept both the `args` and `kwargs` objects, when converting you may specify any signature for these functions that you like. (If your function doesn't support keywords, the parsing

function generated will throw an exception if it receives any.)

Changing and redirecting Clinic's output

It can be inconvenient to have Clinic's output interspersed with your conventional hand-edited C code. Luckily, Clinic is configurable: you can buffer up its output for printing later (or earlier!), or write its output to a separate file. You can also add a prefix or suffix to every line of Clinic's generated output.

While changing Clinic's output in this manner can be a boon to readability, it may result in Clinic code using types before they are defined, or your code attempting to use Clinic-generated code before it is defined. These problems can be easily solved by rearranging the declarations in your file, or moving where Clinic's generated code goes. (This is why the default behavior of Clinic is to output everything into the current block; while many people consider this hampers readability, it will never require rearranging your code to fix definition-before-use problems.)

Let's start with defining some terminology:

field

A field, in this context, is a subsection of Clinic's output. For example, the `#define` for the `PyMethodDef` structure is a field, called `methoddef_define`. Clinic has seven different fields it can output per function definition:

```
docstring_prototype
docstring_definition
methoddef_define
impl_prototype
parser_prototype
parser_definition
impl_definition
```

All the names are of the form `"<a>_<b>"`, where `"<a>"` is the semantic object represented (the parsing function, the impl function, the docstring, or the methoddef structure) and `"<b>"` represents what kind of statement the field is. Field

names that end in `"_prototype"` represent forward declarations of that thing, without the actual body/data of the thing; field names that end in `"_definition"` represent the actual definition of the thing, with the body/data of the thing. (`"methoddef"` is special, it's the only one that ends with `"_define"`, representing that it's a preprocessor #define.)

destination

A destination is a place Clinic can write output to. There are five built-in destinations:

`block`

The default destination: printed in the output section of the current Clinic block.

`buffer`

A text buffer where you can save text for later. Text sent here is appended to the end of any existing text. It's an error to have any text left in the buffer when Clinic finishes processing a file.

`file`

A separate "clinic file" that will be created automatically by Clinic. The filename chosen for the file is `{basename}.clinic{extension}`, where `basename` and `extension` were assigned the output from `os.path.splitext()` run on the current file. (Example: the `file` destination for `_pickle.c` would be written to `_pickle.clinic.c`.)

Important: When using a `file` destination, you *must check in* the generated file!

`two-pass`

A buffer like `buffer`. However, a two-pass buffer can only be dumped once, and it prints out all text sent to it during all processing, even from Clinic blocks *after* the dumping point.

`suppress`

The text is suppressed—thrown away.

Clinic defines five new directives that let you reconfigure its output.

The first new directive is `dump`:

```
dump <destination>
```

This dumps the current contents of the named destination into the output of the current block, and empties it. This only works with `buffer` and `two-pass` destinations.

The second new directive is `output`. The most basic form of `output` is like this:

```
output <field> <destination>
```

This tells Clinic to output *field* to *destination*. `output` also supports a special meta-destination, called `everything`, which tells Clinic to output *all* fields to that *destination*.

`output` has a number of other functions:

```
output push
output pop
output preset <preset>
```

`output push` and `output pop` allow you to push and pop configurations on an internal configuration stack, so that you can temporarily modify the output configuration, then easily restore the previous configuration. Simply push before your change to save the current configuration, then pop when you wish to restore the previous configuration.

`output preset` sets Clinic's output to one of several built-in preset configurations, as follows:

`block`

Clinic's original starting configuration. Writes everything immediately after the input block.

Suppress the `parser_prototype` and `docstring_prototype`, write everything else to `block`.

`file`

Designed to write everything to the "clinic file" that it can. You then `#include` this file near the top of your file. You may need to rearrange your file to make this work, though usually this just means creating forward declarations for various `typedef` and `PyTypeObject` definitions.

Suppress the `parser_prototype` and `docstring_prototype`, write the `impl_definition` to `block`, and write everything else to `file`.

The default filename is `"{dirname}/clinic/{basename}.h"`.

`buffer`

Save up most of the output from Clinic, to be written into your file near the end. For Python files implementing modules or builtin types, it's recommended that you dump the buffer just above the static structures for your module or builtin type; these are normally very near the end. Using `buffer` may require even more editing than `file`, if your file has static `PyMethodDef` arrays defined in the middle of the file.

Suppress the `parser_prototype`, `impl_prototype`, and `docstring_prototype`, write the `impl_definition` to `block`, and write everything else to `file`.

`two-pass`

Similar to the `buffer` preset, but writes forward declarations to the `two-pass` buffer, and definitions to the `buffer`. This is similar to the `buffer` preset, but may require less editing than `buffer`. Dump the `two-pass` buffer near the top of your file, and dump the `buffer` near the end just like you would when using the `buffer` preset.

Suppresses the `impl_prototype`, write the `impl_definition` to `block`, write `docstring_prototype`, `methoddef_define`, and `parser_prototype` to `two-pass`, write everything else to `buffer`.

`partial-buffer`

Similar to the `buffer` preset, but writes more things to `block`, only writing the really big chunks of generated code to `buffer`. This avoids the definition-before-use problem of `buffer` completely, at the small cost of having slightly more stuff in the block's output. Dump the `buffer` near the end, just like you would when using the `buffer` preset.

Suppresses the `impl_prototype`, write the `docstring_definition` and `parser_definition` to `buffer`, write everything else to `block`.

The third new directive is `destination`:

```
destination <name> <command> [...]
```

This performs an operation on the destination named `name`.

There are two defined subcommands: `new` and `clear`.

The `new` subcommand works like this:

`destination <name> new <type>`

This creates a new destination with name `<name>` and type `<type>`.

There are five destination types:

`suppress`
: Throws the text away.

`block`
: Writes the text to the current block. This is what Clinic originally did.

`buffer`
: A simple text buffer, like the “buffer” builtin destination above.

`file`
: A text file. The file destination takes an extra argument, a template to use for building the filename, like so:

    destination <name> new
    <type> <file_template>

  The template can use three strings internally that will be replaced by bits of the filename:

  {path}
  : The full path to the file, including directory and full filename.

  {dirname}
  : The name of the directory the file is in.

  {basename}
  : Just the name of the

file, not including the directory.

{basename_root}
: Basename with the extension clipped off (everything up to but not including the last '.').

{basename_extension}
: The last '.' and everything after it. If the basename does not contain a period, this will be the empty string.

If there are no periods in the filename, {basename} and {filename} are the same, and {extension} is empty. "{basename}{extension}" is always exactly the same as "{filename}"."

`two-pass`
: A two-pass buffer, like the "two-pass" builtin destination above.

The `clear` subcommand works like this:

```
destination <name> clear
```

It removes all the accumulated text up to this point in the destination. (I don't know what you'd need this for, but I thought maybe it'd be useful while someone's experimenting.)

The fourth new directive is `set`:

```
set line_prefix "string"
set line_suffix "string"
```

`set` lets you set two internal variables in Clinic. `line_prefix` is a string that will be prepended to every line of Clinic's output; `line_suffix` is a string that will be appended to every line of Clinic's output.

Both of these support two format strings:

`{block comment start}`
: Turns into the string `/*`, the start-comment text sequence for C files.

`{block comment end}`
: Turns into the string `*/`, the end-comment text sequence for C files.

The final new directive is one you shouldn't need to use directly, called `preserve`:

```
preserve
```

This tells Clinic that the current contents of the output should be kept, unmodified. This is used internally by Clinic when dumping output into `file` files; wrapping it in a Clinic block lets Clinic use its existing checksum functionality to ensure the file was not modified by hand before it gets overwritten.

The #ifdef trick

If you're converting a function that isn't available on all platforms, there's a trick you can use to make life a little easier. The existing code probably looks like this:

```
#ifdef HAVE_FUNCTIONNAME
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

And then in the `PyMethodDef` structure at the bottom the existing code will have:

```
#ifdef HAVE_FUNCTIONNAME
{'functionname', ... },
#endif /* HAVE_FUNCTIONNAME */
```

In this scenario, you should enclose the body of your impl function inside the `#ifdef`, like so:

```
#ifdef HAVE_FUNCTIONNAME
/*[clinic input]
module.functionname
...
[clinic start generated code]*/
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

Then, remove those three lines from the `PyMethodDef` structure, replacing them with the macro Argument Clinic generated:

```
MODULE_FUNCTIONNAME_METHODDEF
```

(You can find the real name for this macro inside the generated code. Or you can calculate it yourself: it's the name of your function as defined on the first line of your block, but with periods changed to underscores, uppercased, and `"_METHODDEF"` added to the end.)

Perhaps you're wondering: what if `HAVE_FUNCTIONNAME` isn't defined? The `MODULE_FUNCTIONNAME_METHODDEF` macro won't be defined either!

Here's where Argument Clinic gets very clever. It actually detects that the Argument Clinic block might be deactivated by the `#ifdef`. When that happens, it generates a little extra code that looks like this:

```
#ifndef MODULE_FUNCTIONNAME_METHODDEF
    #define MODULE_FUNCTIONNAME_METHODDEF
#endif /* !defined(MODULE_FUNCTIONNAME_METHODDEF) */
```

That means the macro always works. If the function is defined, this turns into the correct structure, including the trailing comma. If the function is undefined, this turns into nothing.

However, this causes one ticklish problem: where should Argument Clinic put this extra code when using the "block" output preset? It can't go in the output block, because that could be deactivated by the `#ifdef`. (That's the whole point!)

In this situation, Argument Clinic writes the extra code to the "buffer" destination. This may mean that you get a complaint from Argument Clinic:

```
Warning in file "Modules/posixmodule.c" on line 12357:
Destination buffer 'buffer' not empty at end of file, em
```

When this happens, just open your file, find the `dump buffer` block that Argument Clinic added to your file (it'll be at the very bottom), then move it above the `PyMethodDef` structure where that macro is used.

Using Argument Clinic in Python files

It's actually possible to use Argument Clinic to preprocess Python files. There's no point to using Argument Clinic blocks, of course, as the output wouldn't make any sense to the Python interpreter. But using Argument Clinic to run Python blocks lets you use Python as a Python preprocessor!

Since Python comments are different from C comments, Argument Clinic blocks embedded in Python files look slightly different. They look like this:

```
#/*[python input]
#print("def foo(): pass")
#[python start generated code]*/
def foo(): pass
#/*[python checksum:...]*/
```

Instrumenting CPython with DTrace and SystemTap

author
David Malcolm
author
Łukasz Langa

DTrace and SystemTap are monitoring tools, each providing a way to inspect what the processes on a computer system are doing. They both use domain-specific languages allowing a user to write scripts which:

- filter which processes are to be observed
- gather data from the processes of interest
- generate reports on the data

As of Python 3.6, CPython can be built with embedded "markers", also known as "probes", that can be observed by a DTrace or SystemTap script, making it easier to monitor what the CPython processes on a system are doing.

CPython implementation detail: DTrace markers are implementation details of the CPython interpreter. No guarantees are made about probe compatibility between versions of CPython. DTrace scripts can stop working or work incorrectly without warning when changing CPython versions.

Enabling the static markers

macOS comes with built-in support for DTrace. On Linux, in order to build CPython with the embedded markers for SystemTap, the SystemTap development tools must be installed.

On a Linux machine, this can be done via:

```
$ yum install systemtap-sdt-devel
```

or:

```
$ sudo apt-get install systemtap-sdt-dev
```

CPython must then be **configured with the --with-dtrace option**:

```
checking for --with-dtrace... yes
```

On macOS, you can list available DTrace probes by running a Python process in the background and listing all probes made available by the Python provider:

```
$ python3.6 -q &
$ sudo dtrace -l -P python$!  # or: dtrace -l -m python3

   ID   PROVIDER            MODULE
29564 python18035        python3.6          _PyEval_Eval
29565 python18035        python3.6             dtrace_fu
29566 python18035        python3.6          _PyEval_Eval
29567 python18035        python3.6            dtrace_fun
29568 python18035        python3.6
29569 python18035        python3.6
29570 python18035        python3.6          _PyEval_Eval
29571 python18035        python3.6                maybe
```

On Linux, you can verify if the SystemTap static markers are present in the built binary by seeing if it contains a ".note.stapsdt" section.

```
$ readelf -S ./python | grep .note.stapsdt
[30] .note.stapsdt         NOTE         0000000000000000
```

If you've built Python as a shared library (with the **--enable-shared** configure option), you need to look instead within the shared library. For example:

```
$ readelf -S libpython3.3dm.so.1.0 | grep .note.stapsdt
[29] .note.stapsdt         NOTE         0000000000000000
```

Sufficiently modern readelf can print the metadata:

```
$ readelf -n ./python

        Location: 0x000000000053dba8, Base: 0x0000000000
        Arguments: 8@%rbp 8@%r12 -4@%eax
```

The above metadata contains information for SystemTap describing how it can patch strategically placed machine code instructions to

enable the tracing hooks used by a SystemTap script.

Static DTrace probes

The following example DTrace script can be used to show the call/return hierarchy of a Python script, only tracing within the invocation of a function called “start”. In other words, import-time function invocations are not going to be listed:

```
self int indent;

python$target:::function-entry
/copyinstr(arg1) == "start"/
{
        self->trace = 1;
}

python$target:::function-entry
/self->trace/
{
        printf("%d\t%*s:", timestamp, 15, probename);
        printf("%*s", self->indent, "");
        printf("%s:%s:%d\n", basename(copyinstr(arg0)),
        self->indent++;
}

python$target:::function-return
/self->trace/
{
        self->indent--;
        printf("%d\t%*s:", timestamp, 15, probename);
        printf("%*s", self->indent, "");
        printf("%s:%s:%d\n", basename(copyinstr(arg0)),
}

python$target:::function-return
/copyinstr(arg1) == "start"/
{
```

```
        self->trace = 0;
}
```

It can be invoked like this:

```
$ sudo dtrace -q -s call_stack.d -c "python3.6 script.py
```

The output looks like this:

```
156641360502280  function-entry:call_stack.py:start:23
156641360518804  function-entry: call_stack.py:function_
156641360532797  function-entry:  call_stack.py:function
156641360546807 function-return:  call_stack.py:function

```

Static SystemTap markers

The low-level way to use the SystemTap integration is to use the static markers directly. This requires you to explicitly state the binary file containing them.

For example, this SystemTap script can be used to show the call/return hierarchy of a Python script:

```
probe process("python").mark("function__entry") {
     filename = user_string($arg1);
```

```
      funcname = user_string($arg2);
      lineno = $arg3;

      printf("%s => %s in %s:%d\\n",
             thread_indent(1), funcname, filename, lineno
}

probe process("python").mark("function__return") {
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s <= %s in %s:%d\\n",
           thread_indent(-1), funcname, filename, lineno
}
```

It can be invoked like this:

```
$ stap \
  show-call-hierarchy.stp \
  -c "./python test.py"
```

The output looks like this:

```
11408 python(8274):         => __contains__ in Lib/_abcol
11414 python(8274):          => __getitem__ in Lib/os.py:
11418 python(8274):           => encode in Lib/os.py:490
11424 python(8274):           <= encode in Lib/os.py:493
11428 python(8274):          <= __getitem__ in Lib/os.py:
11433 python(8274):         <= __contains__ in Lib/_abcol
```

where the columns are:

- time in microseconds since start of script
- name of executable
- PID of process

and the remainder indicates the call/return hierarchy as the script executes.

For a **`--enable-shared`** build of CPython, the markers are contained within the libpython shared library, and the probe's dotted path needs to reflect this. For example, this line from the above example:

```
probe process("python").mark("function__entry") {
```

should instead read:

```
probe process("python").library("libpython3.6dm.so.1.0")
```

(assuming a debug build of CPython 3.6)

Available static markers

function_entry(str filename, str funcname, int lineno)

This marker indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

The filename, function name, and line number are provided back to the tracing script as positional arguments, which must be accessed using `$arg1`, `$arg2`, `$arg3`:

- `$arg1` : `(const char *)` filename, accessible using `user_string($arg1)`
- `$arg2` : `(const char *)` function name, accessible using `user_string($arg2)`
- `$arg3` : `int` line number

function_return(str filename, str funcname, int lineno)

This marker is the converse of **`function__entry()`**, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

The arguments are the same as for **`function__entry()`**

line(str filename, str funcname, int lineno)

This marker indicates a Python line is about to be executed. It is the equivalent of line-by-line tracing with a Python profiler. It is not triggered within C functions.

The arguments are the same as for **`function__entry()`**.

gc_start(int generation)

Fires when the Python interpreter starts a garbage collection cycle. `arg0` is the generation to scan, like **`gc.collect()`**.

gc_done(long collected)

Fires when the Python interpreter finishes a garbage collection cycle. `arg0` is the number of collected objects.

import_find_load_start(str modulename)

Fires before **`importlib`** attempts to find and load the module. `arg0` is the module name.

New in version 3.7.

import_find_load_done(str modulename, int found)

Fires after **`importlib`**'s find_and_load function is called. `arg0` is the module name, `arg1` indicates if module was successfully loaded.

New in version 3.7.

audit(str event, void *tuple)

Fires when **`sys.audit()`** or **`PySys_Audit()`** is called. `arg0` is the event name as C string, `arg1` is a **`PyObject`** pointer to a tuple object.

New in version 3.8.

SystemTap Tapsets

The higher-level way to use the SystemTap integration is to use a

"tapset": SystemTap's equivalent of a library, which hides some of the lower-level details of the static markers.

Here is a tapset file, based on a non-shared build of CPython:

```
/*
   Provide a higher-level wrapping around the function__
   function__return markers:
 \*/
probe python.function.entry = process("python").mark("fu
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
probe python.function.return = process("python").mark("f
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
```

If this file is installed in SystemTap's tapset directory (e.g. `/usr/share/systemtap/tapset`), then these additional probepoints become available:

python.function.entry(str filename, str funcname, int lineno, frameptr)

> This probe point indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

python.function.return(str filename, str funcname, int lineno, frameptr)

> This probe point is the converse of `python.function.return`, and indicates that execution of a Python function has ended (either via `return`, or via an

exception). It is only triggered for pure-Python (bytecode) functions.

Examples

This SystemTap script uses the tapset above to more cleanly implement the example given above of tracing the Python function-call hierarchy, without needing to directly name the static markers:

```
probe python.function.entry
{
  printf("%s => %s in %s:%d\n",
         thread_indent(1), funcname, filename, lineno);
}

probe python.function.return
{
  printf("%s <= %s in %s:%d\n",
         thread_indent(-1), funcname, filename, lineno);
}
```

The following script uses the tapset above to provide a top-like view of all running CPython code, showing the top 20 most frequently entered bytecode frames, each second, across the whole system:

```
global fn_calls;

probe python.function.entry
{
    fn_calls[pid(), filename, funcname, lineno] += 1;
}

probe timer.ms(1000) {
    printf("\033[2J\033[1;1H") /* clear screen \*/
    printf("%6s %80s %6s %30s %6s\n",
           "PID", "FILENAME", "LINE", "FUNCTION", "CALLS
    foreach ([pid, filename, funcname, lineno] in fn_cal
        printf("%6d %80s %6d %30s %6d\n",
            pid, filename, lineno, funcname,
```

```
            fn_calls[pid, filename, funcname, lineno]);
    }
    delete fn_calls;
}
```

Annotations Best Practices

author

Larry Hastings

Abstract

This document is designed to encapsulate the best practices for working with annotations dicts. If you write Python code that examines `__annotations__` on Python objects, we encourage you to follow the guidelines described below.

The document is organized into four sections: best practices for accessing the annotations of an object in Python versions 3.10 and newer, best practices for accessing the annotations of an object in Python versions 3.9 and older, other best practices for `__annotations__` that apply to any Python version, and quirks of `__annotations__`.

Note that this document is specifically about working with `__annotations__`, not uses *for* annotations. If you're looking for information on how to use "type hints" in your code, please see the **`typing`** module.

Accessing The Annotations Dict Of An Object In Python 3.10 And Newer

Python 3.10 adds a new function to the standard library: **`inspect.get_annotations()`**. In Python versions 3.10 and newer, calling this function is the best practice for accessing the annotations dict of any object that supports annotations. This function can also "un-stringize" stringized annotations for you.

If for some reason `inspect.get_annotations()` isn't viable for your use case, you may access the `__annotations__` data member manually. Best practice for this changed in Python 3.10 as well: as of Python 3.10, `o.__annotations__` is guaranteed to *always* work on Python functions, classes, and modules. If you're certain the object you're examining is one of these three *specific* objects, you may simply use `o.__annotations__` to get at the object's annotations dict.

However, other types of callables–for example, callables created by `functools.partial()`–may not have an `__annotations__` attribute defined. When accessing the `__annotations__` of a possibly unknown object, best practice in Python versions 3.10 and newer is to call `getattr()` with three arguments, for example `getattr(o, '__annotations__', None)`.

Accessing The Annotations Dict Of An Object In Python 3.9 And Older

In Python 3.9 and older, accessing the annotations dict of an object is much more complicated than in newer versions. The problem is a design flaw in these older versions of Python, specifically to do with class annotations.

Best practice for accessing the annotations dict of other objects–functions, other callables, and modules–is the same as best practice for 3.10, assuming you aren't calling `inspect.get_annotations()`: you should use three-argument `getattr()` to access the object's `__annotations__` attribute.

Unfortunately, this isn't best practice for classes. The problem is that, since `__annotations__` is optional on classes, and because classes can inherit attributes from their base classes, accessing the `__annotations__` attribute of a class may inadvertently return the annotations dict of a *base class.* As an example:

```
class Base:
    a: int = 3
    b: str = 'abc'

class Derived(Base):
    pass

print(Derived.__annotations__)
```

This will print the annotations dict from `Base`, not `Derived`.

Your code will have to have a separate code path if the object you're examining is a class (`isinstance(o, type)`). In that case, best practice relies on an implementation detail of Python 3.9 and before: if a class has annotations defined, they are stored in the class's `__dict__` dictionary. Since the class may or may not have annotations defined, best practice is to call the `get` method on the class dict.

To put it all together, here is some sample code that safely accesses the `__annotations__` attribute on an arbitrary object in Python 3.9 and before:

```
if isinstance(o, type):
    ann = o.__dict__.get('__annotations__', None)
else:
    ann = getattr(o, '__annotations__', None)
```

After running this code, `ann` should be either a dictionary or `None`. You're encouraged to double-check the type of `ann` using **`isinstance()`** before further examination.

Note that some exotic or malformed type objects may not have a `__dict__` attribute, so for extra safety you may also wish to use **`getattr()`** to access `__dict__`.

Manually Un-Stringizing Stringized Annotations

In situations where some annotations may be "stringized", and you wish to evaluate those strings to produce the Python values they represent, it really is best to call **`inspect.get_annotations()`** to do this work for you.

If you're using Python 3.9 or older, or if for some reason you can't use **`inspect.get_annotations()`**, you'll need to duplicate its logic. You're encouraged to examine the implementation of **`inspect.get_annotations()`** in the current Python version and follow a similar approach.

In a nutshell, if you wish to evaluate a stringized annotation on an arbitrary object `o`:

- If `o` is a module, use `o.__dict__` as the `globals` when calling **`eval()`**.
- If `o` is a class, use `sys.modules[o.__module__].__dict__` as the `globals`, and `dict(vars(o))` as the `locals`, when calling **`eval()`**.
- If `o` is a wrapped callable using **`functools.update_wrapper()`**, **`functools.wraps()`**, or

functools.partial(), iteratively unwrap it by accessing either `o.__wrapped__` or `o.func` as appropriate, until you have found the root unwrapped function.
- If `o` is a callable (but not a class), use `o.__globals__` as the globals when calling **eval()**.

However, not all string values used as annotations can be successfully turned into Python values by **eval()**. String values could theoretically contain any valid string, and in practice there are valid use cases for type hints that require annotating with string values that specifically *can't* be evaluated. For example:

- **PEP 604** [https://peps.python.org/pep-0604/] union types using `|`, before support for this was added to Python 3.10.
- Definitions that aren't needed at runtime, only imported when **typing.TYPE_CHECKING** is true.

If **eval()** attempts to evaluate such values, it will fail and raise an exception. So, when designing a library API that works with annotations, it's recommended to only attempt to evaluate string values when explicitly requested to by the caller.

Best Practices For `__annotations__` In Any Python Version

- You should avoid assigning to the `__annotations__` member of objects directly. Let Python manage setting `__annotations__`.
- If you do assign directly to the `__annotations__` member of an object, you should always set it to a `dict` object.

- If you directly access the `__annotations__` member of an object, you should ensure that it's a dictionary before attempting to examine its contents.
- You should avoid modifying `__annotations__` dicts.
- You should avoid deleting the `__annotations__` attribute of an object.

`__annotations__` Quirks

In all versions of Python 3, function objects lazy-create an annotations dict if no annotations are defined on that object. You can delete the `__annotations__` attribute using `del fn.__annotations__`, but if you then access `fn.__annotations__` the object will create a new empty dict that it will store and return as its annotations. Deleting the annotations on a function before it has lazily created its annotations dict will throw an `AttributeError`; using `del fn.__annotations__` twice in a row is guaranteed to always throw an `AttributeError`.

Everything in the above paragraph also applies to class and module objects in Python 3.10 and newer.

In all versions of Python 3, you can set `__annotations__` on a function object to `None`. However, subsequently accessing the annotations on that object using `fn.__annotations__` will lazy-create an empty dictionary as per the first paragraph of this section. This is *not* true of modules and classes, in any Python version; those objects permit setting `__annotations__` to any Python value, and will retain whatever value is set.

If Python stringizes your annotations for you (using `from __future__ import annotations`), and you specify a string as an annotation, the string will

itself be quoted. In effect the annotation is quoted *twice*. For example:

```
from __future__ import annotations
def foo(a: "str"): pass

print(foo.__annotations__)
```

This prints `{'a': "'str'"}`. This shouldn't really be considered a "quirk"; it's mentioned here simply because it might be surprising.

Isolating Extension Modules

Abstract

Traditionally, state belonging to Python extension modules was kept in C `static` variables, which have process-wide scope. This document describes problems of such per-process state and shows a safer way: per-module state.

The document also describes how to switch to per-module state where possible. This transition involves allocating space for that state, potentially switching from static types to heap types, and —perhaps most importantly—accessing per-module state from code.

Who should read this

This guide is written for maintainers of C-API extensions who would like to make that extension safer to use in applications where Python itself is used as a library.

Background

An *interpreter* is the context in which Python code runs. It contains configuration (e.g. the import path) and runtime state (e.g. the set of imported modules).

Python supports running multiple interpreters in one process. There are two cases to think about—users may run interpreters:

- in sequence, with several **`Py_InitializeEx()`**/**`Py_FinalizeEx()`** cycles, and
- in parallel, managing "sub-interpreters" using **`Py_NewInterpreter()`**/**`Py_EndInterpreter()`**.

Both cases (and combinations of them) would be most useful when embedding Python within a library. Libraries generally shouldn't make assumptions about the application that uses them, which include assuming a process-wide "main Python interpreter".

Historically, Python extension modules don't handle this use case well. Many extension modules (and even some stdlib modules) use *per-process* global state, because C `static` variables are extremely easy to use. Thus, data that should be specific to an interpreter ends up being shared between interpreters. Unless the extension developer is careful, it is very easy to introduce edge cases that lead to crashes when a module is loaded in more than one interpreter in the same process.

Unfortunately, *per-interpreter* state is not easy to achieve. Extension authors tend to not keep multiple interpreters in mind when developing, and it is currently cumbersome to test the behavior.

Enter Per-Module State

Instead of focusing on per-interpreter state, Python's C API is evolving to better support the more granular *per-module* state. This means that C-level data is be attached to a *module object*. Each interpreter creates its own module object, keeping the data separate. For testing the isolation, multiple module objects corresponding to a single extension can even be loaded in a single interpreter.

Per-module state provides an easy way to think about lifetime and resource ownership: the extension module will initialize when a module object is created, and clean up when it's freed. In this regard, a module is just like any other PyObject*; there are no "on interpreter shutdown" hooks to think—or forget—about.

Note that there are use cases for different kinds of "globals": per-process, per-interpreter, per-thread or per-task state. With per-module state as the default, these are still possible, but you should treat them as exceptional cases: if you need them, you should give them additional care and testing. (Note that this guide does not cover them.)

Isolated Module Objects

The key point to keep in mind when developing an extension module is that several module objects can be created from a single shared library. For example:

```
>>> import sys
>>> import binascii
>>> old_binascii = binascii
>>> del sys.modules['binascii']
>>> import binascii  # create a new module object
>>> old_binascii == binascii
False
```

As a rule of thumb, the two modules should be completely independent. All objects and state specific to the module should be encapsulated within the module object, not shared with other module objects, and cleaned up when the module object is deallocated. Since this just is a rule of thumb, exceptions are possible (see Managing Global State), but they will need more thought and attention to edge cases.

While some modules could do with less stringent restrictions, isolated modules make it easier to set clear expectations and guidelines that work across a variety of use cases.

Surprising Edge Cases

Note that isolated modules do create some surprising edge cases. Most notably, each module object will typically not share its classes and exceptions with other similar modules. Continuing from the example above, note that `old_binascii.Error` and `binascii.Error` are separate objects. In the following code, the exception is *not* caught:

```
>>> old_binascii.Error == binascii.Error
False
>>> try:
...     old_binascii.unhexlify(b'qwertyuiop')
... except binascii.Error:
```

```
...     print('boo')
...
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
binascii.Error: Non-hexadecimal digit found
```

This is expected. Notice that pure-Python modules behave the same way: it is a part of how Python works.

The goal is to make extension modules safe at the C level, not to make hacks behave intuitively. Mutating `sys.modules` "manually" counts as a hack.

Making Modules Safe with Multiple Interpreters

Managing Global State

Sometimes, the state associated with a Python module is not specific to that module, but to the entire process (or something else "more global" than a module). For example:

- The `readline` module manages *the* terminal.
- A module running on a circuit board wants to control *the* on-board LED.

In these cases, the Python module should provide *access* to the global state, rather than *own* it. If possible, write the module so that multiple copies of it can access the state independently (along with other libraries, whether for Python or other languages). If that is not possible, consider explicit locking.

If it is necessary to use process-global state, the simplest way to avoid issues with multiple interpreters is to explicitly prevent a module from being loaded more than once per process—see Opt-Out: Limiting to One Module Object per Process.

Managing Per-Module State

To use per-module state, use multi-phase extension module initialization. This signals that your module supports multiple interpreters correctly.

Set `PyModuleDef.m_size` to a positive number to request that many bytes of storage local to the module. Usually, this will be set to the size of some module-specific `struct`, which can store all of the module's C-level state. In particular, it is where you should put pointers to classes (including exceptions, but excluding static types) and settings (e.g. `csv`'s **`field_size_limit`**) which the C code needs to function.

Note

Another option is to store state in the module's `__dict__`, but you must avoid crashing when users modify `__dict__` from Python code. This usually means error- and type-checking at the C level, which is easy to get wrong and hard to test sufficiently.

However, if module state is not needed in C code, storing it in `__dict__` only is a good idea.

If the module state includes `PyObject` pointers, the module object must hold references to those objects and implement the module-level hooks `m_traverse`, `m_clear` and `m_free`. These work like `tp_traverse`, `tp_clear` and `tp_free` of a class. Adding them will require some work and make the code longer; this is the price for modules which can be unloaded cleanly.

An example of a module with per-module state is currently available as xxlimited [https://github.com/python/cpython/blob/master/Modules/xxlimited.c]; example module initialization shown at the bottom of the file.

Opt-Out: Limiting to One Module Object per Process

A non-negative `PyModuleDef.m_size` signals that a module supports multiple interpreters correctly. If this is not yet the case for your module, you can explicitly make your module loadable only once per process. For example:

```
static int loaded = 0;

static int
exec_module(PyObject* module)
{
    if (loaded) {
        PyErr_SetString(PyExc_ImportError,
                        "cannot load module more than or
        return -1;
    }
    loaded = 1;
    // ... rest of initialization
}
```

Module State Access from Functions

Accessing the state from module-level functions is straightforward. Functions get the module object as their first argument; for extracting the state, you can use `PyModule_GetState`:

```
static PyObject *
func(PyObject *module, PyObject *args)
{
    my_struct *state = (my_struct*)PyModule_GetState(moc
    if (state == NULL) {
        return NULL;
    }
    // ... rest of logic
}
```

Note

`PyModule_GetState` may return `NULL` without setting an exception if there is no module state, i.e. `PyModuleDef.m_size` was zero. In your own module, you're in control of `m_size`, so this is easy to prevent.

Heap Types

Traditionally, types defined in C code are *static*; that is, `static PyTypeObject` structures defined directly in code and initialized using `PyType_Ready()`.

Such types are necessarily shared across the process. Sharing them between module objects requires paying attention to any state they own or access. To limit the possible issues, static types are immutable at the Python level: for example, you can't set `str.myattribute = 123`.

CPython implementation detail: Sharing truly immutable objects between interpreters is fine, as long as they don't provide access to mutable objects. However, in CPython, every Python object has a mutable implementation detail: the reference count. Changes to the refcount are guarded by the GIL. Thus, code that shares any Python objects across interpreters implicitly depends on CPython's current, process-wide GIL.

Because they are immutable and process-global, static types cannot access "their" module state. If any method of such a type requires access to module state, the type must be converted to a *heap-allocated type*, or *heap type* for short. These correspond more closely to classes created by Python's `class` statement.

For new modules, using heap types by default is a good rule of thumb.

Changing Static Types to Heap Types

Static types can be converted to heap types, but note that the heap type API was not designed for "lossless" conversion from static types—that is, creating a type that works exactly like a given static type. So, when rewriting the class definition in a new API, you are likely to unintentionally change a few details (e.g. pickleability or inherited slots). Always test the details that are important to you.

Watch out for the following two points in particular (but note that this is not a comprehensive list):

- Unlike static types, heap type objects are mutable by default. Use the **`Py_TPFLAGS_IMMUTABLETYPE`** flag to prevent

mutability.
- Heap types inherit **tp_new** by default, so it may become possible to instantiate them from Python code. You can prevent this with the **Py_TPFLAGS_DISALLOW_INSTANTIATION** flag.

Defining Heap Types

Heap types can be created by filling a **PyType_Spec** structure, a description or "blueprint" of a class, and calling **PyType_FromModuleAndSpec()** to construct a new class object.

Note

Other functions, like **PyType_FromSpec()**, can also create heap types, but **PyType_FromModuleAndSpec()** associates the module with the class, allowing access to the module state from methods.

The class should generally be stored in *both* the module state (for safe access from C) and the module's `__dict__` (for access from Python code).

Garbage-Collection Protocol

Instances of heap types hold a reference to their type. This ensures that the type isn't destroyed before all its instances are, but may result in reference cycles that need to be broken by the garbage collector.

To avoid memory leaks, instances of heap types must implement the garbage collection protocol. That is, heap types should:

- Have the **Py_TPFLAGS_HAVE_GC** flag.
- Define a traverse function using `Py_tp_traverse`, which visits the type (e.g. using Py_VISIT(Py_TYPE(self))).

Please refer to the the documentation of **Py_TPFLAGS_HAVE_GC** and **tp_traverse** for additional considerations.

If your traverse function delegates to the `tp_traverse` of its base class (or another type), ensure that `Py_TYPE(self)` is visited only once. Note that only heap type are expected to visit the type in `tp_traverse`.

For example, if your traverse function includes:

```
base->tp_traverse(self, visit, arg)
```

…and `base` may be a static type, then it should also include:

```
if (base->tp_flags & Py_TPFLAGS_HEAPTYPE) {
    // a heap type's tp_traverse already visited Py_TYPE
} else {
    Py_VISIT(Py_TYPE(self));
}
```

It is not necessary to handle the type's reference count in `tp_new` and `tp_clear`.

Module State Access from Classes

If you have a type object defined with **`PyType_FromModuleAndSpec()`**, you can call **`PyType_GetModule()`** to get the associated module, and then **`PyModule_GetState()`** to get the module's state.

To save a some tedious error-handling boilerplate code, you can combine these two steps with **`PyType_GetModuleState()`**, resulting in:

```
my_struct *state = (my_struct*)PyType_GetModuleState(typ
if (state === NULL) {
    return NULL;
}
```

Module State Access from Regular Methods

Accessing the module-level state from methods of a class is somewhat more complicated, but is possible thanks to API

introduced in Python 3.9. To get the state, you need to first get the *defining class*, and then get the module state from it.

The largest roadblock is getting *the class a method was defined in*, or that method's "defining class" for short. The defining class can have a reference to the module it is part of.

Do not confuse the defining class with Py_TYPE(self). If the method is called on a *subclass* of your type, `Py_TYPE(self)` will refer to that subclass, which may be defined in different module than yours.

Note

The following Python code can illustrate the concept. `Base.get_defining_class` returns `Base` even if `type(self) == Sub`:

```
class Base:
    def get_type_of_self(self):
        return type(self)

    def get_defining_class(self):
        return __class__

class Sub(Base):
    pass
```

For a method to get its "defining class", it must use the **`METH_METHOD | METH_FASTCALL | METH_KEYWORDS`** **`calling convention`** and the corresponding **`PyCMethod`** signature:

```
PyObject *PyCMethod(
    PyObject *self,                // object the method w
    PyTypeObject *defining_class, // defining class
    PyObject *const *args,         // C array of argument
    Py_ssize_t nargs,              // length of "args"
    PyObject *kwnames)             // NULL, or dict of ke
```

Once you have the defining class, call

PyType_GetModuleState() to get the state of its associated module.

For example:

```
static PyObject *
example_method(PyObject *self,
        PyTypeObject *defining_class,
        PyObject *const *args,
        Py_ssize_t nargs,
        PyObject *kwnames)
{
    my_struct *state = (my_struct*)PyType_GetModuleState
    if (state === NULL) {
        return NULL;
    }
    ... // rest of logic
}

PyDoc_STRVAR(example_method_doc, "...");

static PyMethodDef my_methods[] = {
    {"example_method",
      (PyCFunction)(void(*)(void))example_method,
      METH_METHOD|METH_FASTCALL|METH_KEYWORDS,
      example_method_doc}
    {NULL},
}
```

Module State Access from Slot Methods, Getters and Setters

Note

This is new in Python 3.11.

Slot methods—the fast C equivalents for special methods, such as **nb_add** for **__add__** or **tp_new** for initialization—have a very

simple API that doesn't allow passing in the defining class, unlike with **PyCMethod**. The same goes for getters and setters defined with **PyGetSetDef**.

To access the module state in these cases, use the **PyType_GetModuleByDef()** function, and pass in the module definition. Once you have the module, call **PyModule_GetState()** to get the state:

```
PyObject *module = PyType_GetModuleByDef(Py_TYPE(self),
my_struct *state = (my_struct*)PyModule_GetState(module)
if (state === NULL) {
    return NULL;
}
```

`PyType_GetModuleByDef` works by searching the method resolution order (i.e. all superclasses) for the first superclass that has a corresponding module.

Note

In very exotic cases (inheritance chains spanning multiple modules created from the same definition), `PyType_GetModuleByDef` might not return the module of the true defining class. However, it will always return a module with the same definition, ensuring a compatible C memory layout.

Lifetime of the Module State

When a module object is garbage-collected, its module state is freed. For each pointer to (a part of) the module state, you must hold a reference to the module object.

Usually this is not an issue, because types created with **PyType_FromModuleAndSpec()**, and their instances, hold a reference to the module. However, you must be careful in reference counting when you reference module state from other places, such as callbacks for external libraries.

Open Issues

Several issues around per-module state and heap types are still open.

Discussions about improving the situation are best held on the capi-sig mailing list [https://mail.python.org/mailman3/lists/capi-sig.python.org/].

Per-Class Scope

It is currently (as of Python 3.11) not possible to attach state to individual *types* without relying on CPython implementation details (which may change in the future—perhaps, ironically, to allow a proper solution for per-class scope).

Lossless Conversion to Heap Types

The heap type API was not designed for “lossless” conversion from static types; that is, creating a type that works exactly like a given static type.

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. It supports multiple programming paradigms beyond object-oriented programming, such as procedural and functional programming. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants including Linux and macOS, and on Windows.

To find out more, start with The Python Tutorial. The Beginner's Guide to Python [https://wiki.python.org/moin/BeginnersGuide] links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF's mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF's home page is at https://www.python.org/psf/.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the PSF donation page

[https://www.python.org/psf/donations/].

Are there copyright restrictions on the use of Python?

You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the PSF license page [https://www.python.org/psf/license/] to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy [https://www.python.org/psf/trademarks/] for more information.

Why was Python created in the first place?

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

> I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).
>
> I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of

Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the `Misc/HISTORY` file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), internet protocols (HTTP, FTP, SMTP,

XML-RPC, POP, IMAP), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for The Python Standard Library to get an idea of what's available. A wide variety of third-party extensions are also available. Consult the Python Package Index [https://pypi.org] to find packages of interest to you.

How does the Python version numbering scheme work?

Python versions are numbered "A.B.C" or "A.B":

- *A* is the major version number – it is only incremented for really major changes in the language.
- *B* is the minor version number – it is incremented for less earth-shattering changes.
- *C* is the micro version number – it is incremented for each bugfix release.

See **PEP 6** [https://peps.python.org/pep-0006/] for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix:

- The suffix for an alpha version is "aN" for some small number *N*.
- The suffix for a beta version is "bN" for some small number *N*.
- The suffix for a release candidate version is "rcN" for some

small number *N*.

In other words, all versions labeled *2.0aN* precede the versions labeled *2.0bN*, which precede versions labeled *2.0rcN*, and *those* precede 2.0.

You may also find version numbers with a "+" suffix, e.g. "2.2+". These are unreleased versions, built directly from the CPython development repository. In practice, after a final minor release is made, the version is incremented to the next minor version, which becomes the "a0" version, e.g. "2.4a0".

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

How do I obtain a copy of the Python source?

The latest Python source distribution is always available from python.org, at https://www.python.org/downloads/. The latest development sources can be obtained at https://github.com/python/cpython/.

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the Getting Started section of the Python Developer's Guide [https://devguide.python.org/setup/] for more information on getting the source code and compiling it.

How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at https://docs.python.org/3/. PDF, plain text, and downloadable HTML versions are also available at https://docs.python.org/3/download.html.

The documentation is written in reStructuredText and processed by the Sphinx documentation tool [https://www.sphinx-doc.org/]. The

reStructuredText source for the documentation is part of the Python source distribution.

I've never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes The Python Tutorial.

Consult the Beginner's Guide [https://wiki.python.org/moin/BeginnersGuide] to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, python-list [https://mail.python.org/mailman/listinfo/python-list]. The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in comp.lang.python.announce, a low-traffic moderated list that receives about five postings per day. It's available as the python-announce mailing list [https://mail.python.org/mailman/listinfo/python-announce-list].

More info about other mailing lists and newsgroups can be found at https://www.python.org/community/lists/.

How do I get a beta test version of Python?

Alpha and beta releases are available from https://www.python.org/downloads/. All releases are announced on the comp.lang.python and comp.lang.python.announce newsgroups and on the Python home page at https://www.python.org/; an RSS feed of news is available.

You can also access the development version of Python through Git. See The Python Developer's Guide [https://devguide.python.org/] for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, use the issue tracker at https://github.com/python/cpython/issues.

For more information on how Python is developed, consult the Python Developer's Guide [https://devguide.python.org/].

Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The very first article about Python was written in 1991 and is now quite outdated.

> Guido van Rossum and Jelke de Boer, "Interactively Testing Remote Servers Using the Python Programming Language", CWI Quarterly, Volume 4, Issue 4 (December 1991), Amsterdam, pp 283–303.

Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at https://wiki.python.org/moin/PythonBooks for a list.

You can also search online bookstores for "Python" and filter out the Monty Python references; or perhaps search for "Python" and "language".

Where in the world is www.python.org located?

The Python project's infrastructure is located all over the world and is managed by the Python Infrastructure Team. Details here [https://

infra.psf.io].

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from "Monty Python's Flying Circus" [https://en.wikipedia.org/wiki/Monty_Python], a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

Do I have to like "Monty Python's Flying Circus"?

No, but it helps. :)

Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. As of version 3.9, Python will have a major new release every 12 months (**PEP 602** [https://peps.python.org/pep-0602/]).

The developers issue "bugfix" releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 3.5.3, 3.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it's guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page [https://www.python.org/downloads/]. There are two production-ready versions of Python: 2.x and 3.x. The recommended version is 3.x, which is supported by most widely used libraries. Although 2.x is still widely used, it is not maintained anymore [https://peps.python.org/pep-0373/].

How many people are using Python?

There are probably millions of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don't tell the whole story either.

The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

Have any significant projects been done in Python?

See https://www.python.org/about/success for a list of projects that use Python. Consulting the proceedings for past Python conferences [https://www.python.org/community/workshops/] will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager [https://www.list.org] and the Zope application server [https://www.zope.dev]. Several Linux distributions, most notably Red Hat [https://www.redhat.com], have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

What new developments are expected for Python in the future?

See https://peps.python.org/ for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled "Python X.Y Release Schedule", where X.Y is a version that hasn't been publicly released yet.

New development is discussed on the python-dev mailing list [https://mail.python.org/mailman/listinfo/python-dev/].

Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there's still the problem of updating all documentation; many books have been written about Python, and we don't want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** [https://peps.python.org/pep-0005/] describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be

assigned programming projects very early in the course that *do* something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['__add__', '__class__', '__contains__', '__delattr__',
'__dir__', '__doc__', '__eq__', '__format__', '__ge__',
'__getattribute__', '__getitem__', '__gt__', '__hash__',
'__imul__', '__init__', '__iter__', '__le__', '__len__',
'__mul__', '__ne__', '__new__', '__reduce__', '__reduce_
'__repr__', '__reversed__', '__rmul__', '__setattr__', '
'__sizeof__', '__str__', '__subclasshook__', 'append', '
'copy', 'count', 'extend', 'index', 'insert', 'pop', 're
'reverse', 'sort']
>>> [d for d in dir(L) if '__' not in d]
['append', 'clear', 'copy', 'count', 'extend', 'index',

>>> help(L.append)
Help on built-in function append:

append(...)
    L.append(object) -> None -- append object to end

>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as they are programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult the Python wiki [https://wiki.python.org/moin/PythonEditors] for a full list of Python editing environments.

If you want to discuss Python's use in education, you may be interested in joining the edu-sig mailing list [https://www.python.org/community/sigs/current/edu-sig].

- What is a method?
- What is self?
- How do I check if an object is an instance of a given class or of a subclass of it?
- What is delegation?
- How do I call a method defined in a base class from a derived class that extends it?
- How can I organize my code to make it easier to change the base class?
- How do I create static class data and static class methods?
- How can I overload constructors (or methods) in Python?
- I try to use _spam and I get an error about _SomeClassName_spam.
- My class defines _del_ but it is not called when I delete the object.
- How do I get a list of all instances of a given class?
- Why does the result of `id()` appear to be not unique?
- When can I rely on identity tests with the *is* operator?
- How can a subclass control what data is stored in an immutable instance?
- How do I cache method calls?

- Modules
  - How do I create a .pyc file?
  - How do I find the current module name?
  - How can I have modules that mutually import each other?
  - _import_('x.y.z') returns <module 'x'>; how do I get z?
  - When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

Several debuggers for Python are described below, and the built-in function `breakpoint()` allows you to drop into any of them.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is `documented in the Library Reference Manual`. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle3 [https://github.com/python/cpython/blob/main/Tools/scripts/idle3]), includes a graphical debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The PythonWin debugger colors breakpoints and has quite a few cool features such as debugging non-PythonWin programs. PythonWin is available as part of pywin32 [https://github.com/mhammond/pywin32] project and as a part of the ActivePython [https://www.activestate.com/products/python/] distribution.

Eric [https://eric-ide.python-projects.org/] is an IDE built on PyQt and the

Scintilla editing component.

trepan3k [https://github.com/rocky/python3-trepan/] is a gdb-like debugger.

Visual Studio Code [https://code.visualstudio.com/] is an IDE with debugging tools that integrates with version-control software.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE [https://wingware.com/]
- Komodo IDE [https://www.activestate.com/products/komodo-ide/]
- PyCharm [https://www.jetbrains.com/pycharm/]

Are there tools to help find bugs or perform static analysis?

Yes.

Pylint [https://pylint.pycqa.org/en/latest/index.html] and Pyflakes [https://github.com/PyCQA/pyflakes] do basic checking that will help you catch bugs sooner.

Static type checkers such as Mypy [http://mypy-lang.org/], Pyre [https://pyre-check.org/], and Pytype [https://github.com/google/pytype] can check type hints in Python source code.

How can I create a stand-alone binary from a Python script?

You don't need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as Tools/freeze [https://github.com/python/cpython/tree/main/Tools/freeze]. It converts Python byte code to C arrays; with a C compiler

you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

The following packages can help with the creation of console and GUI executables:

- Nuitka [https://nuitka.net/] (Cross-platform)
- PyInstaller [https://pyinstaller.org/] (Cross-platform)

Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as **PEP 8** [https://peps.python.org/pep-0008/].

Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the `UnboundLocalError` in previously working code when it is modified by adding an assignment

statement somewhere in the body of a function.

This code:

```
>>> x = 10
>>> def bar():
...     print(x)
...
>>> bar()
10
```

works, but this code:

```
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an **`UnboundLocalError`**:

```
>>> foo()
Traceback (most recent call last):
  ...
UnboundLocalError: local variable 'x' referenced before
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in foo assigns a new value to `x`, the compiler recognizes it as a local variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
...
```

```
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```
>>> print(x)
11
```

You can do a similar thing in a nested scope using the **`nonlocal`** keyword:

```
>>> def foo():
...     x = 10
...     def bar():
...         nonlocal x
...         print(x)
...         x += 1
...     bar()
...     print(x)
...
>>> foo()
10
11
```

What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a value anywhere within the function's body, it's assumed to be a local unless explicitly declared as global.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring **`global`** for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you'd be using `global` all the time. You'd have to declare as global every

reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

Why do lambdas defined in a loop with different values all return the same result?

Assume you use a for loop to define a few different lambdas (or even plain functions), e.g.:

```
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You might expect that, when called, they would return, respectively, `0`, `1`, `4`, `9`, and `16`. However, when you actually try you will see that they all return `16`:

```
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is `4`, so all the functions now return `4**2`, i.e. `16`. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```
>>> x = 8
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don't rely on the value of the global `x`:

```
>>> squares = []
>>> for x in range(5):
```

```
...      squares.append(lambda n=x: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be `0` in the first lambda, `1` in the second, `2` in the third, and so on. Therefore each lambda will now return the correct result:

```
>>> squares[2]()
4
>>> squares[4]()
16
```

Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

How do I share global variables across modules?

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

config.py:

```
x = 0   # Default value of the 'x' configuration setting
```

mod.py:

```
import config
config.x = 1
```

main.py:

```
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the

singleton design pattern, for the same reason.

What are the "best practices" for using import in a module?

In general, don't use `from modulename import *`. Doing so clutters the importer's namespace, and makes it much harder for linters to detect undefined names.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It's good practice if you import modules in the following order:

1. standard library modules – e.g. **`sys`**, **`os`**, **`argparse`**, **`re`**
2. third-party library modules (anything installed in Python's site-packages directory) – e.g. **`dateutil`**, **`requests`**, **`PIL.Image`**
3. locally developed modules

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

> Circular imports are fine where both modules use the "import <module>" form of import. They fail when the 2nd module wants to grab a name out of the first ("from module import name") and the import is at the top level. That's because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it

may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in **`sys.modules`**.

Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```
def foo(mydict={}):  # Danger: shared reference to one d
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don't write:

```
def foo(mydict={}):
    ...
```

but:

```
def foo(mydict=None):
    if mydict is None:
        mydict = {}  # create a new dict for local names
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called "memoizing", and can be implemented like this:

```
# Callers can only provide two parameters and optionally
def expensive(arg1, arg2, *, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ... expensive computation ...
    _cache[(arg1, arg2)] = result           # Store resu
    return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.

How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the `*` and `**` specifiers in the function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then

pass these arguments when calling another function by using `*` and `**`:

```
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    g(x, *args, **kwargs)
```

What is the difference between arguments and parameters?

Parameters are defined by the names that appear in a function definition, whereas arguments are the values actually passed to a function when calling it. Parameters define what kind of arguments a function can accept. For example, given the function definition:

```
def func(foo, bar=None, **kwargs):
    pass
```

foo, *bar* and *kwargs* are parameters of `func`. However, when calling `func`, for example:

```
func(42, bar=314, extra=somevar)
```

the values `42`, `314`, and `somevar` are arguments.

Why did changing list 'y' also change list 'x'?

If you wrote code like:

```
>>> x = []
>>> y = x
>>> y.append(10)
>>> y
[10]
>>> x
[10]
```

you might be wondering why appending an element to `y` changed

`x` too.

There are two factors that produce this result:

1. Variables are simply names that refer to objects. Doing `y = x` doesn't create a copy of the list – it creates a new variable `y` that refers to the same object `x` refers to. This means that there is only one object (the list), and both `x` and `y` refer to it.
2. Lists are mutable, which means that you can change their content.

After the call to **`append()`**, the content of the mutable object has changed from `[]` to `[10]`. Since both the variables refer to the same object, using either name accesses the modified value `[10]`.

If we instead assign an immutable object to `x`:

```
>>> x = 5  # ints are immutable
>>> y = x
>>> x = x + 1  # 5 can't be mutated, we are creating a r
>>> x
6
>>> y
5
```

we can see that in this case `x` and `y` are not equal anymore. This is because integers are immutable, and when we do `x = x + 1` we are not mutating the int `5` by incrementing its value; instead, we are creating a new object (the int `6`) and assigning it to `x` (that is, changing which object `x` refers to). After this assignment we have two objects (the ints `6` and `5`) and two variables that refer to them (`x` now refers to `6` but `y` still refers to `5`).

Some operations (for example `y.append(10)` and `y.sort()`) mutate the object, whereas superficially similar operations (for example `y = y + [10]` and **`sorted(y)`**) create a new object. In general in Python (and in all cases in the standard library) a method that mutates an object will return `None` to help avoid getting the two types of operations confused. So if you mistakenly write `y.sort()` thinking it will give you a sorted copy of `y`, you'll

instead end up with `None`, which will likely cause your program to generate an easily diagnosed error.

However, there is one class of operations where the same operation sometimes has different behaviors with different types: the augmented assignment operators. For example, `+=` mutates lists but not tuples or ints (`a_list += [1, 2, 3]` is equivalent to `a_list.extend([1, 2, 3])` and mutates `a_list`, whereas `some_tuple += (1, 2, 3)` and `some_int += 1` create new objects).

In other words:

- If we have a mutable object (**`list`**, **`dict`**, **`set`**, etc.), we can use some specific operations to mutate it and all the variables that refer to it will see the change.
- If we have an immutable object (**`str`**, **`int`**, **`tuple`**, etc.), all the variables that refer to it will always see the same value, but operations that transform that value into a new value always return a new object.

If you want to know if two variables refer to the same object or not, you can use the **`is`** operator, or the built-in function **`id()`**.

How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

```
>>> def func1(a, b):
...     a = 'new-value'        # a and b are local
...     b = b + 1              # assigned to new ob
...     return a, b            # return new values
...
```

```
>>> x, y = 'old-value', 99
>>> func1(x, y)
('new-value', 100)
```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```
>>> def func2(a):
...     a[0] = 'new-value'     # 'a' references a m
...     a[1] = a[1] + 1        # changes a shared o
...
>>> args = ['old-value', 99]
>>> func2(args)
>>> args
['new-value', 100]
```

4. By passing in a dictionary that gets mutated:

```
>>> def func3(args):
...     args['a'] = 'new-value'     # args is a mut
...     args['b'] = args['b'] + 1   # change it in-
...
>>> args = {'a': 'old-value', 'b': 99}
>>> func3(args)
>>> args
{'a': 'new-value', 'b': 100}
```

5. Or bundle up values in a class instance:

```
>>> class Namespace:
...     def __init__(self, /, **args):
...         for key, value in args.items():
...             setattr(self, key, value)
...
>>> def func4(args):
...     args.a = 'new-value'        # args is a mut
```

```
...     args.b = args.b + 1         # change object
...
>>> args = Namespace(a='old-value', b=99)
>>> func4(args)
>>> vars(args)
{'a': 'new-value', 'b': 100}
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```
class linear:

    def __init__(self, a, b):
        self.a, self.b = a, b

    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit

slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```
class counter:

    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

How do I copy an object in Python?

In general, try **`copy.copy()`** or **`copy.deepcopy()`** for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a **`copy()`** method:

```
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```
new_l = l[:]
```

How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, **`dir(x)`** returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can't, because objects don't really have names. Essentially, assignment always binds a name to a value; the same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
>>> class A:
...     pass
...
>>> B = A
>>> a = B()
>>> b = a
>>> print(b)
<__main__.A object at 0x16D07CC>
>>> print(a)
<__main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name `B` the created instance is still reported as an instance of class `A`. However, it is impossible to say whether the instance's name is `a` or `b`, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to "know the names" of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

> The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn't really care – so the only way to find out what it's called is to ask all your neighbours (namespaces) if it's their cat (object)…
>
> ….and don't be surprised if you'll find that it's known by many names, or no name at all!

What's up with the comma operator's precedence?

Comma is not an operator in Python. Consider this session:

```
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```
("a" in "b"), "a"
```

not:

```
"a" in ("b", "a")
```

The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

Is there an equivalent of C's "?:" ternary operator?

Yes, there is. The syntax is as follows:

```
[on_true] if [expression] else [on_false]

x, y = 50, 25
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when *on_true* has a false boolean value. Therefore, it is always better to use the `... if ... else ...` form.

Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting `lambda` within `lambda`. See the following three examples, slightly adapted from Ulf Bartelt:

```
from functools import reduce

# Primes < 1000
print(list(filter(None,map(lambda y:y*reduce(lambda x,y:
map(lambda x,y=y:y%x,range(2,int(pow(y,0.5)+1))),1),rang

# First 10 Fibonacci numbers
print(list(map(lambda x,f=lambda x,f:(f(x-1,f)+f(x-2,f))
f(x,f), range(10))))

# Mandelbrot set
print((lambda Ru,Ro,Iu,Io,IM,Sx,Sy:reduce(lambda x,y:x+'
Iu=Iu,Io=Io,Ru=Ru,Ro=Ro,Sy=Sy,L=lambda yc,Iu=Iu,Io=Io,Ru
Sx=Sx,Sy=Sy:reduce(lambda x,y:x+y,map(lambda x,xc=Ru,yc=
i=i,Sx=Sx,F=lambda xc,yc,x,y,k,f=lambda xc,yc,x,y,k,f:(k
>=4.0) or 1+f(xc,yc,x*x-y*y+xc,2.0*x*y+yc,k-1,f):f(xc,yc
64+F(Ru+x*(Ro-Ru)/Sx,yc,0,0,i)),range(Sx))):L(Iu+y*(Io-I
))))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))
#     \___ ___/  \___ ___/  |   |   |__ lines on screen
#         V          V      |   |______ columns on screen
#         |          |      |_________ maximum of "itera
#         |          |________________ range on y axis
#         |___________________________ range on x axis
```

Don't try this at home, kids!

What does the slash(/) in the parameter list of a

function mean?

A slash in the argument list of a function denotes that the parameters prior to it are positional-only. Positional-only parameters are the ones without an externally usable name. Upon calling a function that accepts positional-only parameters, arguments are mapped to parameters based solely on their position. For example, `divmod()` is a function that accepts positional-only parameters. Its documentation looks like this:

```
>>> help(divmod)
Help on built-in function divmod in module builtins:

divmod(x, y, /)
    Return the tuple (x//y, x%y).  Invariant: div*y + mo
```

The slash at the end of the parameter list means that both parameters are positional-only. Thus, calling `divmod()` with keyword arguments would lead to an error:

```
>>> divmod(x=3, y=4)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: divmod() takes no keyword arguments
```

Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”.

Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

Why does -22 // 10 return -3?

It's primarily driven by the desire that `i % j` have the same sign as `j`. If you want that, and also want:

```
i == (i // j) * j + (i % j)
```

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate `i // j` need to make `i % j` have the same sign as `i`.

There are few real use cases for `i % j` when `j` is negative. When `j` is positive, there are many, and in virtually all of them it's more useful for `i % j` to be `>= 0`. If the clock says 10 now, what did it say 200 hours ago? `-190 % 12 == 2` is useful; `-190 % 12 == -10` is a bug waiting to bite.

How do I get int literal attribute instead of SyntaxError?

Trying to lookup an `int` literal attribute in the normal manner gives a **`SyntaxError`** because the period is seen as a decimal point:

```
>>> 1.__class__
  File "<stdin>", line 1
  1.__class__
   ^
SyntaxError: invalid decimal literal
```

The solution is to separate the literal from the period with either a space or parentheses.

```
>>> 1 .__class__
<class 'int'>
>>> (1).__class__
<class 'int'>
```

How do I convert a string to a number?

For integers, use the built-in **`int()`** type constructor, e.g. `int('144') == 144`. Similarly, **`float()`** converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` holds true, and `int('0x144')` raises **`ValueError`**. `int(string, base)` takes the base to convert from as a second optional argument, so `int( '0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0o' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function **`eval()`** if all you need is to convert strings to numbers. **`eval()`** will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python does not allow leading '0' in a decimal number (except '0').

How do I convert a number to a string?

To convert, e.g., the number `144` to the string `'144'`, use the built-in type constructor **`str()`**. If you want a hexadecimal or octal representation, use the built-in functions **`hex()`** or **`oct()`**. For fancy formatting, see the Formatted string literals and Format String Syntax sections, e.g. `"{:04d}".format(144)` yields

`'0144'` and `"{:.3f}".format(1.0/3.0)` yields `'0.333'`.

How do I modify a string in place?

You can't, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using an **`io.StringIO`** object or the **`array`** module:

```
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
>>> print(a)
array('u', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('u', 'yello, world')
>>> a.tounicode()
'yello, world'
```

How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the

primary technique used to emulate a case construct:

```
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b}  # Note lack of par

dispatch[get_input()]()  # Note trailing parens to
```

- Use the built-in function **`getattr()`**:

  ```
  import foo
  getattr(foo, 'bar')()
  ```

  Note that **`getattr()`** works on any object, including classes, class instances, modules, and so on.

  This is used in several places in the standard library, like this:

  ```
  class Foo:
      def do_foo(self):
          ...

      def do_bar(self):
          ...

  f = getattr(foo_instance, 'do_' + opname)
  f()
  ```

- Use **`locals()`** to resolve the function name:

  ```
  def myFunc():
      print("hello")

  fname = "myFunc"

  f = locals()[fname]
  ```

```
f()
```

Is there an equivalent to Perl's chomp() for removing trailing newlines from strings?

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other trailing whitespace. If the string `S` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```
>>> lines = ("line 1 \r\n"
...          "\r\n"
...          "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '
```

Since this is typically only desired when reading text one line at a time, using `S.rstrip()` this way works well.

Is there a scanf() or sscanf() equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the **`split()`** method of string objects and then convert decimal strings to numeric values using **`int()`** or **`float()`**. **`split()`** supports an optional "sep" parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C's `sscanf` and better suited for the task.

What does 'UnicodeDecodeError' or 'UnicodeEncodeError' error mean?

See the Unicode HOWTO.

Performance

My program is too slow. How do I speed it up?

That's a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focuses on CPython.
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program *before* attempting to optimize any code (see the `profile` module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the `timeit` module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the Built-in Types and the `collections` module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the `list.sort()` built-in method or the related `sorted()` function to do sorting (and see the Sorting HOW TO for examples of moderately advanced usage).
- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be

slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, Cython [https://cython.org] can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also write a C extension module yourself.

What is the most efficient way to concatenate many strings together?

`str` and **`bytes`** objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many **`str`** objects, the recommended idiom is to place them into a list and call **`str.join()`** at the end:

```
chunks = []
for s in my_strings:
    chunks.append(s)
result = ''.join(chunks)
```

(another reasonably efficient idiom is to use **`io.StringIO`**)

To accumulate many **`bytes`** objects, the recommended idiom is to extend a **`bytearray`** object using in-place concatenation (the `+=` operator):

```
result = bytearray()
for b in my_bytes_objects:
    result += b
```

Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call **`tuple()`** when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[:-1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

How do I iterate over a sequence in reverse order?

Use the **`reversed()`** built-in function:

```
for x in reversed(sequence):
    ...  # do something with x ...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

https://code.activestate.com/recipes/52560/

If you don't mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```

If all elements of the list may be used as set keys (i.e. they are all hashable) this is often faster

```
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

How do you remove multiple items from a list

As with removing duplicates, explicitly iterating in reverse with a delete condition is one possibility. However, it is easier and faster to use slice replacement with an implicit or explicit forward iteration. Here are three variations.:

```
mylist[:] = filter(keep_function, mylist)
```

```
mylist[:] = (x for x in mylist if keep_condition)
mylist[:] = [x for x in mylist if keep_condition]
```

The list comprehension may be fastest.

How do you make an array in Python?

Use a list:

```
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that NumPy [https://numpy.org/] and other third party packages define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate *cons cells* using tuples:

```
lisp_list = ("like",  ("this",  ("example", None) ) )
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of a Lisp *car* is `lisp_list[0]` and the analogue of *cdr* is `lisp_list[1]`. Only do this if you're sure you really need to, because it's usually a lot slower than using Python lists.

How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; NumPy [https://numpy.org/] is the best known.

How do I apply a method or function to a sequence of objects?

To call a method or function and accumulate the return values is a list, a list comprehension is an elegant solution:

```
result = [obj.method() for obj in mylist]

result = [function(obj) for obj in mylist]
```

To just run the method or function without saving the return values, a plain `for` loop will suffice:

```
for obj in mylist:
    obj.method()

for obj in mylist:
    function(obj)
```

Why does a_tuple[i] += ['item'] raise an exception when the addition works?

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we'll use a `list` and `+=` as our exemplar.

If you wrote:

```
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
   ...
TypeError: 'tuple' object does not support item assignme
```

The reason for the exception should be immediately clear: `1` is added to the object `a_tuple[0]` points to (`1`), producing the result object, `2`, but when we attempt to assign the result of the computation, `2`, to element `0` of the tuple, we get an error because we can't change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignme
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```
>>> a_tuple = (['foo'], 'bar')
>>> a_tuple[0] += ['item']
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignme
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an **`__iadd__()`** magic method, it gets called when the += augmented assignment is executed, and its return value is what gets used in the assignment statement; and (b) for lists, **`__iadd__()`** is equivalent to calling **`extend()`** on the list and returning the list. That's why we say that for lists, `+=` is a "shorthand" for **`list.extend()`**:

```
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by a_list has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignme
```

The **`__iadd__()`** succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its "sort value". In Python, use the `key` argument for the **`list.sort()`** method:

```
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```
>>> list1 = ["what", "I'm", "sorting", "by"]
>>> list2 = ["something", "else", "to", "sort"]
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[("I'm", 'else'), ('by', 'sort'), ('sorting', 'to'), ('w
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic `Mailbox` class that provides basic accessor methods for a mailbox, and subclasses such as `MboxMailbox`, `MaildirMailbox`, `OutlookMailbox` that handle various specific mailbox formats.

What is a method?

A method is a function on some object `x` that you normally call as `x.name(arguments...)`. Methods are defined as functions inside the class definition:

```
class C:
    def meth(self, arg):
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also Why must 'self' be used explicitly in method definitions and calls?.

How do I check if an object is an instance of a given

class or of a subclass of it?

Use the built-in function **`isinstance(obj, cls)`**. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python's built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that **`isinstance()`** also checks for virtual inheritance from an abstract base class. So, the test will return `True` for a registered class even if hasn't directly or indirectly inherited from it. To test for "true inheritance", scan the MRO of the class:

```
from collections.abc import Mapping

class P:
     pass

class C(P):
    pass

Mapping.register(P)
```

```
>>> c = C()
>>> isinstance(c, C)        # direct
True
>>> isinstance(c, P)        # indirect
True
>>> isinstance(c, Mapping)  # virtual
True

# Actual inheritance chain
>>> type(c).__mro__
(<class 'C'>, <class 'P'>, <class 'object'>)

# Test for "true inheritance"
>>> Mapping in type(c).__mro__
False
```

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object's class and doing a different thing based on what class it is. For example, if you have a function that does something:

```
def search(obj):
    if isinstance(obj, Mailbox):
        ...  # code to search a mailbox
    elif isinstance(obj, Document):
        ...  # code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```
class Mailbox:
    def search(self):
        ...  # code to search a mailbox

class Document:
    def search(self):
        ...  # code to search a document

obj.search()
```

What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```
class UpperOut:

    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
        return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the **`__getattr__()`** method; consult the language reference for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a **`__setattr__()`** method too, and it must do so carefully. The basic implementation of **`__setattr__()`** is roughly equivalent to the following:

```
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most **`__setattr__()`** implementations must modify **`self.__dict__`** to store local state for self without causing an infinite recursion.

How do I call a method defined in a base class from a derived class that extends it?

Use the built-in **`super()`** function:

```
class Derived(Base):
    def meth(self):
        super().meth()  # calls Base.meth
```

In the example, `super()` will automatically determine the instance from which it was called (the `self` value), look up the method resolution order (MRO) with `type(self).__mro__`, and return the next in line after `Derived` in the MRO: `Base`.

How can I organize my code to make it easier to change the base class?

You could assign the base class to an alias and derive from the alias. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```
class Base:
    ...

BaseAlias = Base

class Derived(BaseAlias):
    ...
```

How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```
class C:
    count = 0   # number of times C.__init__ called
```

```
    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

`c.count` also refers to `C.count` for any `c` such that `isinstance(c, C)` holds, unless overridden by `c` itself or by some class on the base-class search path from `c.__class__` back to `C`.

Caution: within a method of C, an assignment like `self.count = 42` creates a new and unrelated instance named "count" in `self`'s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```
C.count = 314
```

Static methods are possible:

```
class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

```
def getcount():
    return C.count
```

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you'd write

```
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

```
def __init__(self, *args):
    ...
```

The same approach works for all method definitions.

I try to use _spam and I get an error about _SomeClassName_spam.

Variable names with double leading underscores are "mangled" to provide a simple but effective way to define class private variables. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `_classname__spam`, where `classname` is the current class name with any leading underscores stripped.

This doesn't guarantee privacy: an outside user can still deliberately access the "_classname_spam" attribute, and private values are visible in the object's `__dict__`. Many Python programmers never bother to use private variable names at all.

My class defines _del_ but it is not called when I delete the object.

There are several possible reasons for this.

The `del` statement does not necessarily call `__del__()` – it simply decrements the object's reference count, and if this reaches zero `__del__()` is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your `__del__()` method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's `__del__()` methods are executed is arbitrary. You can run `gc.collect()` to force a collection, but there *are* pathological cases where objects will never be collected.

Despite the cycle collector, it's still a good idea to define an explicit `close()` method on objects to be called whenever you're done with them. The `close()` method can then remove attributes that refer to subobjects. Don't call `__del__()` directly – `__del__()` should call `close()` and `close()` should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the `weakref` module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your `__del__()` method raises an exception, a warning message is printed to `sys.stderr`.

How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-

in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.

Why does the result of `id()` appear to be not unique?

The `id()` builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object's memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```

When can I rely on identity tests with the *is* operator?

The `is` operator tests for object identity. The test `a is b` is equivalent to `id(a) == id(b)`.

The most important property of an identity test is that an object is always identical to itself, `a is a` always returns `True`. Identity tests are usually faster than equality tests. And unlike equality tests, identity tests are guaranteed to return a boolean `True` or `False`.

However, identity tests can *only* be substituted for equality tests when object identity is assured. Generally, there are three

circumstances where identity is guaranteed:

1) Assignments create new names but do not change object identity. After the assignment `new = old`, it is guaranteed that `new is old`.

2) Putting an object in a container that stores object references does not change object identity. After the list assignment `s[0] = x`, it is guaranteed that `s[0] is x`.

3) If an object is a singleton, it means that only one instance of that object can exist. After the assignments `a = None` and `b = None`, it is guaranteed that `a is b` because `None` is a singleton.

In most other circumstances, identity tests are inadvisable and equality tests are preferred. In particular, identity tests should not be used to check constants such as **`int`** and **`str`** which aren't guaranteed to be singletons:

```
>>> a = 1000
>>> b = 500
>>> c = b + 500
>>> a is c
False

>>> a = 'Python'
>>> b = 'Py'
>>> c = b + 'thon'
>>> a is c
False
```

Likewise, new instances of mutable containers are never identical:

```
>>> a = []
>>> b = []
>>> a is b
False
```

In the standard library code, you will see several common patterns for correctly using identity tests:

1) As recommended by **PEP 8** [https://peps.python.org/pep-0008/], an identity test is the preferred way to check for `None`. This reads like plain English in code and avoids confusion with other objects that may have boolean values that evaluate to false.

2) Detecting optional arguments can be tricky when `None` is a valid input value. In those situations, you can create a singleton sentinel object guaranteed to be distinct from other objects. For example, here is how to implement a method that behaves like **`dict.pop()`**:

```
_sentinel = object()

def pop(self, key, default=_sentinel):
    if key in self:
        value = self[key]
        del self[key]
        return value
    if default is _sentinel:
        raise KeyError(key)
    return default
```

3) Container implementations sometimes need to augment equality tests with identity tests. This prevents the code from being confused by objects such as `float('NaN')` that are not equal to themselves.

For example, here is the implementation of **`collections.abc.Sequence.__contains__()`**:

```
def __contains__(self, value):
    for v in self:
        if v is value or v == value:
            return True
    return False
```

How can a subclass control what data is stored in an immutable instance?

When subclassing an immutable type, override the **`__new__()`**

method instead of the **`__init__()`** method. The latter only runs *after* an instance is created, which is too late to alter data in an immutable instance.

All of these immutable classes have a different signature than their parent class:

```
from datetime import date

class FirstOfMonthDate(date):
    "Always choose the first day of the month"
    def __new__(cls, year, month, day):
        return super().__new__(cls, year, month, 1)

class NamedInt(int):
    "Allow text names for some numbers"
    xlat = {'zero': 0, 'one': 1, 'ten': 10}
    def __new__(cls, value):
        value = cls.xlat.get(value, value)
        return super().__new__(cls, value)

class TitleStr(str):
    "Convert str to name suitable for a URL path"
    def __new__(cls, s):
        s = s.lower().replace(' ', '-')
        s = ''.join([c for c in s if c.isalnum() or c ==
        return super().__new__(cls, s)
```

The classes can be used like this:

```
>>> FirstOfMonthDate(2012, 2, 14)
FirstOfMonthDate(2012, 2, 1)
>>> NamedInt('ten')
10
>>> NamedInt(20)
20
>>> TitleStr('Blog: Why Python Rocks')
'blog-why-python-rocks'
```

How do I cache method calls?

The two principal tools for caching methods are **`functools.cached_property()`** and **`functools.lru_cache()`**. The former stores results at the instance level and the latter at the class level.

The *cached_property* approach only works with methods that do not take any arguments. It does not create a reference to the instance. The cached method result will be kept only as long as the instance is alive.

The advantage is that when an instance is no longer used, the cached method result will be released right away. The disadvantage is that if instances accumulate, so too will the accumulated method results. They can grow without bound.

The *lru_cache* approach works with methods that have hashable arguments. It creates a reference to the instance unless special efforts are made to pass in weak references.

The advantage of the least recently used algorithm is that the cache is bounded by the specified *maxsize*. The disadvantage is that instances are kept alive until they age out of the cache or until the cache is cleared.

This example shows the various techniques:

```
class Weather:
    "Lookup weather information on a government website"

    def __init__(self, station_id):
        self._station_id = station_id
        # The _station_id is private and immutable

    def current_temperature(self):
        "Latest hourly observation"
        # Do not cache this because old results
        # can be out of date.
```

```
    @cached_property
    def location(self):
        "Return the longitude/latitude coordinates of th
        # Result only depends on the station_id

    @lru_cache(maxsize=20)
    def historic_rainfall(self, date, units='mm'):
        "Rainfall on a given date"
        # Depends on the station_id, date, and units.
```

The above example assumes that the *station_id* never changes. If the relevant instance attributes are mutable, the *cached_property* approach can't be made to work because it cannot detect changes to the attributes.

To make the *lru_cache* approach work when the *station_id* is mutable, the class needs to define the **`__eq__()`** and **`__hash__()`** methods so that the cache can detect relevant attribute updates:

```
class Weather:
    "Example with a mutable station identifier"

    def __init__(self, station_id):
        self.station_id = station_id

    def change_station(self, station_id):
        self.station_id = station_id

    def __eq__(self, other):
        return self.station_id == other.station_id

    def __hash__(self):
        return hash(self.station_id)

    @lru_cache(maxsize=20)
    def historic_rainfall(self, date, units='cm'):
        'Rainfall on a given date'
        # Depends on the station_id, date, and units.
```

Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a `.pyc` file containing the compiled code should be created in a `__pycache__` subdirectory of the directory containing the `.py` file. The `.pyc` file will have a filename that starts with the same name as the `.py` file, and ends with `.pyc`, with a middle component that depends on the particular `python` binary that created it. (See **PEP 3147** [https://peps.python.org/pep-3147/] for details.)

One reason that a `.pyc` file may not be created is a permissions problem with the directory containing the source file, meaning that the `__pycache__` subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the **`PYTHONDONTWRITEBYTECODE`** environment variable is set, creation of a .pyc file is automatic if you're importing a module and Python has the ability (permissions, free space, etc…) to create a `__pycache__` subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no `.pyc` will be created. For example, if you have a top-level module `foo.py` that imports another module `xyz.py`, when you run `foo` (by typing `python foo.py` as a shell command), a `.pyc` will be created for `xyz` because `xyz` is imported, but no `.pyc` file will be created for `foo` since `foo.py` isn't being imported.

If you need to create a `.pyc` file for `foo` – that is, to create a `.pyc` file for a module that is not imported – you can, using the **`py_compile`** and **`compileall`** modules.

The **`py_compile`** module can manually compile any module. One way is to use the `compile()` function in that module interactively:

```
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the `.pyc` to a `__pycache__` subdirectory in the same location as `foo.py` (or you can override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the **`compileall`** module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```
def main():
    print('Running test...')
    ...

if __name__ == '__main__':
    main()
```

How can I have modules that mutually import each other?

Suppose you have the following modules:

`foo.py`:

```
from bar import bar_var
foo_var = 1
```

`bar.py`:

```
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports `foo`
- Empty globals for `foo` are created
- `foo` is compiled and starts executing
- `foo` imports `bar`
- Empty globals for `bar` are created
- `bar` is compiled and starts executing
- `bar` imports `foo` (which is a no-op since there already is a module named `foo`)
- The import mechanism tries to read `foo_var` from `foo` globals, to set `bar.foo_var = foo.foo_var`

The last step fails, because Python isn't done with interpreting `foo` yet and the global symbol dictionary for `foo` is still empty.

The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements
- active code (including globals that are initialized from imported values).

Van Rossum doesn't like this approach much because the imports

appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

import('x.y.z') returns <module 'x'>; how do I get z?

Consider using the convenience function `import_module()` from `importlib` instead:

```
z = importlib.import_module('x.y.z')
```

When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be updated to use the new class definition. This can result in the following paradoxical behaviour:

```
>>> import importlib
```

```
>>> import cls
>>> c = cls.C()                # Create an instance of C
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C)       # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the "identity" of the class objects:

```
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```

Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
        x++;
        y--;
z++;
```

Only the `x++` statement is executed if the condition is true, but the indentation leads many to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering as to why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place

the braces. After becoming used to reading and writing code using a particular style, it is normal to feel somewhat uneasy when reading (or being required to write) in a different one.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20–30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.

Why am I getting strange results with simple arithmetic operations?

See the next question.

Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The **`float`** type in CPython uses a C `double` for storage. A **`float`** object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation

cannot be expressed exactly in binary floating-point. For example, after:

```
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value `1.2`, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011 (
```

which is exactly:

```
1.1999999999999999555910790149937383830547332763671875 (
```

The typical precision of 53 bits provides Python floats with 15–16 decimal digits of accuracy.

For a fuller explanation, please see the floating point arithmetic chapter in the Python tutorial.

Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.

Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don't know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you'd have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>)`. This is particularly useful for **`__init__()`** methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren't explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.

Why can't I use an assignment in an expression?

Starting in Python 3.8, you can!

Assignment expressions using the walrus operator `:=` assign a variable in an expression:

```
while chunk := fp.read(200):
   print(chunk)
```

See **PEP 572** [https://peps.python.org/pep-0572/] for more information.

Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?

As Guido said:

> (a) For some operations, prefix notation just reads better than postfix – prefix (and infix!) operations have a long tradition in mathematics which likes notations where the visuals help the mathematician thinking about a problem. Compare the easy with which we rewrite a formula like x*(a+b) into x*a + x*b to the clumsiness of doing the same thing using a raw OO notation.
>
> (b) When I read code that says len(x) I *know* that it is asking for the length of something. This tells me two things: the result is an integer, and the argument is some kind of container. To the contrary, when I read x.len(), I have to already know that x is some kind of container implementing an interface or inheriting from a class that has a standard len(). Witness the confusion we occasionally have when a class that is not implementing a mapping has a get() or keys() method, or something that isn't a file has a write() method.

python-3000/2006-November/004643.html

Why is join() a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having **`split()`** as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(", ")
```

is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself

between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.

How fast are exceptions?

A try/except block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn't the case, you coded it like this:

```
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.

Why isn't there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. For literal values, or constants within a namespace, you can also use a `match ... case` statement.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to

functions to call. For example:

```
functions = {'a': function_1,
             'b': function_2,
             'c': self.method_1}

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```
class MyVisitor:
    def visit_a(self):
        ...

    def dispatch(self, value):
        method_name = 'visit_' + str(value)
        method = getattr(self, method_name)
        method()
```

It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.

Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python [https://github.com/stackless-dev/stackless/wiki], which has a completely redesigned interpreter loop that avoids the C stack.

Why can't lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally defined function is that you don't need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!

Can Python be compiled to machine code, C or some other language?

Cython [https://cython.org/] compiles a modified version of Python with optional annotations into C extensions. Nuitka [https://www.nuitka.net/] is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, CPython, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as Jython [https://www.jython.org] or PyPy [https://www.pypy.org]), however, can rely on a different

mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to *f* closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the **`with`** statement; this will work regardless of memory management scheme:

```
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
```

Why doesn't CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it's not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn't completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it's fine to replace the standard malloc() and free() with versions provided by the GC library, an application embedding Python may want to have its *own* substitute for malloc() and free(), and may not want Python's. Right now, CPython works with anything that implements

malloc() and free() properly.

Why isn't all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.

Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can't replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements.

Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.

How are lists implemented in CPython?

CPython's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list `a[i]` an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.

How are dictionaries implemented in CPython?

CPython's dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the **`hash()`** built-in function. The hash code varies widely depending on the key and a per-process seed; for example, "Python" could hash to -539294296 while "python", a string that differs by a single bit, could hash to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time – O(1), in Big-O notation – to retrieve a key.

Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

  ```
  mydict = {[1, 2]: '12'}
  print(mydict[[1, 2]])
  ```

  would raise a **`KeyError`** exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using **`is`**.

- Make a copy when using a list as a key. This doesn't work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it's not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a **`__eq__()`** and a **`__hash__()`** method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list

    def __eq__(self, other):
        return self.the_list == other.the_list

    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                result = result + (hash(el) % 9999999) *
            except Exception:
                result = (result % 7777777) + i * 333
        return result
```

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2) is True`) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`), regardless of whether the

object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of ListWrapper, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don't do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.

Why doesn't list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won't be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here's how to iterate over the keys of a dictionary in sorted order:

```
for key in sorted(mydict):
    ...  # do whatever with mydict[key]...
```

How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and

issubclass() to check whether an instance or a class implements a particular ABC. The **collections.abc** module defines a set of useful ABCs such as **Iterable**, **Container**, and **MutableMapping**.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple "self test." Even modules which use complex external interfaces can often be tested in isolation using trivial "stub" emulations of the external interface. The **doctest** and **unittest** modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the **append()** method is expected to add new elements to the end of some internal list; an interface specification cannot test that your **append()** implementation will actually do this correctly, but it's trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code to make it easily tested. One increasingly popular technique, test-driven development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.

Why is there no goto?

In the 1970s people realized that unrestricted goto could lead to messy "spaghetti" code that was hard to understand and revise. In a high-level language, it is also unneeded as long as there are ways to branch (in Python, with `if` statements and `or`, `and`, and `if-else` expressions) and loop (with `while` and `for` statements, possibly containing `continue` and `break`).

One can also use exceptions to provide a “structured goto” that works even across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```
class label(Exception): pass  # declare a label

try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
...
```

This doesn’t allow you to jump into the middle of a loop, but that’s usually considered an abuse of goto anyway. Use sparingly.

Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```
f = open("/mydir/file.txt")  # works fine!
```

If you’re trying to build a pathname for a DOS command, try e.g.

one of

```
dir = r"\this\is\my\dos\dir" "\\"
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```

Why doesn't Python have a "with" statement for attribute assignments?

Python has a 'with' statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some languages have a construct that looks like this:

```
with obj:
    a = 1               # equivalent to obj.a = 1
    total = total + 1   # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it's possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler *always* knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```
def foo(a):
    with a:
        print(x)
```

The snippet assumes that "a" must have a member attribute called "x". However, there is nothing in Python that tells the interpreter this. What should happen if "a" is, let us say, an integer? If there is

a global variable named “x”, will it be used inside the with block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.

Why don’t generators support the with statement?

For technical reasons, a generator used directly as a context manager would not work correctly. When, as is most common, a generator is used as an iterator run to completion, no closing is needed. When it is, wrap it as “contextlib.closing(generator)” in the ‘with’ statement.

Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
    print(a)
```

versus

```
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.

Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional but
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [
  "fee",
  "fie"
  "foo",
  "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check the Library Reference to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the Python Package Index [https://pypi.org] or try Google [https://www.google.com] or another web search engine. Searching for "Python" plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.)

source file?

If you can't find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like `mathmodule.c`, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:

   ```
   import sys
   print(sys.builtin_module_names)
   ```

How do I make a Python script executable on Unix?

You need to do two things: the script file's mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the **env** program. Almost all Unix variants support the following, assuming the Python interpreter is

in a directory on the user's **PATH**:

```
#!/usr/bin/env python
```

Don't do this for CGI scripts. The **PATH** variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the **/usr/bin/env** program fails; or there's no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```
#! /bin/sh
""":"
exec python $0 ${1+"$@"}
"""
```

The minor disadvantage is that this defines the script's _doc_ string. However, you can fix that by adding

```
__doc__ = """...Whatever..."""
```

Is there a curses/termcap package for Python?

For Unix variants: The standard Python source distribution comes with a curses module in the Modules [https://github.com/python/cpython/tree/3.11/Modules] subdirectory, though it's not compiled by default. (Note that this is not available in the Windows distribution – there is no curses module for Windows.)

The **curses** module supports basic curses features as well as many additional functions from ncurses and SYSV curses such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD curses, but there don't seem to be any currently maintained OSes that fall into this category.

Is there an equivalent to C's onexit() in Python?

The **atexit** module provides a register function that is similar to C's **onexit()**.

Why don’t my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two parameters:

```
def handler(signum, frame):
    ...
```

Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The **`doctest`** module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The **`unittest`** module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```
if __name__ == "__main__":
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of function and class behaviours, you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it's surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the "production code", since this makes it easy to find bugs and even design flaws earlier.

"Support modules" that are not intended to be the main module of a program may include a self-test of the module.

```
if __name__ == "__main__":
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using "fake" interfaces implemented in Python.

How do I create documentation from doc strings?

The **pydoc** module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is epydoc [https://epydoc.sourceforge.net/]. Sphinx [https://www.sphinx-doc.org] can also include docstring content.

How do I get a single keypress at a time?

For Unix variants there are several solutions. It's straightforward to do this using curses, but curses is a fairly large module to learn.

Threads

How do I program using threads?

Be sure to use the **threading** module and not the **_thread** module. The **threading** module builds convenient abstractions on top of the low-level primitives provided by the **_thread** module.

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i
    T.start()

time.sleep(10)   # <---------------------------!
```

But now (on many platforms) the threads don't run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn't start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```
def thread_task(name, n):
    time.sleep(0.001)   # <--------------------!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for **`time.sleep()`**,

it's better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

How do I parcel out work among a bunch of worker threads?

The easiest way is to use the `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue and a `.get()` method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```
import threading, queue, time

# The worker thread gets jobs off the queue.  When the q
# assumes there will be no more work and exits.
# (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.current_thread(),
            print('queue empty')
            break
        else:
            print('Worker', threading.current_thread(),
            print('running with argument', arg)
```

```
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker %i'
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)

# Give threads time to run
print('Main thread sleeping')
time.sleep(5)
```

When run, this will produce the following output:

```
Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> runni
Worker <Thread(worker 2, started 130283824404752)> runni
Worker <Thread(worker 3, started 130283816012048)> runni
Worker <Thread(worker 4, started 130283807619344)> runni
Worker <Thread(worker 5, started 130283799226640)> runni
Worker <Thread(worker 1, started 130283832797456)> runni
...
```

Consult the module's documentation for more details; the `Queue` class provides a featureful interface.

What kinds of global value mutation are thread-safe?

A global interpreter lock (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via **`sys.setswitchinterval()`**. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that "look atomic" really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren't:

```
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects' **`__del__()`** method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

Can't we get rid of the Global Interpreter Lock?

The global interpreter lock (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the "free threading" patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his python-safethread [https://code.google.com/archive/p/python-safethread] project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn't mean that you can't make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The `ProcessPoolExecutor` class in the new `concurrent.futures` module provides an easy way of doing so; the `multiprocessing` module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as `zlib` and `hashlib` already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn't be able to share objects. Unfortunately, this isn't likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter

state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?

Input and Output

How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the **`os`** module. The two functions are identical; **`unlink()`** is simply the name of the Unix system call for this function.

To remove a directory, use **`os.rmdir()`**; use **`os.mkdir()`** to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use **`shutil.rmtree()`**.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`; offset defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with **`os.open()`**, where *fd* is the file descriptor (a small integer).

The **`shutil`** module also contains a number of functions to work on files including **`copyfile()`**, **`copytree()`**, and **`rmtree()`**.

How do I copy a file?

The **shutil** module contains a **copyfile()** function. Note that on Windows NTFS volumes, it does not copy alternate data streams [https://en.wikipedia.org/wiki/NTFS#Alternate_data_stream_(ADS)] nor resource forks [https://en.wikipedia.org/wiki/Resource_fork] on macOS HFS+ volumes, though both are now rarely used. It also doesn't copy file permissions and metadata, though using **shutil.copy2()** instead will preserve most (though not all) of it.

How do I read (or write) binary data?

To read or write complex binary data formats, it's best to use the **struct** module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The '>' in the format string forces big-endian data; the letter 'h' reads one "short integer" (2 bytes), and 'l' reads one "long integer" (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the **array** module.

Note

To read and write binary data, it is mandatory to open the file in binary mode (here, passing `"rb"` to **open()**). If you use `"r"` instead (the default), the file will be open in text mode and `f.read()` will return **str** objects rather than **bytes** objects.

I can't seem to use os.read() on a pipe created with

os.popen(); why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()` function. Thus, to read *n* bytes from a pipe *p* created with `os.popen()`, you need to use `p.read(n)`.

How do I access the serial (RS232) port?

For Win32, OSX, Linux, BSD, Jython, IronPython:

> https://pypi.org/project/pyserial/

For Unix, see a Usenet post by Mitch Chapman:

> https://groups.google.com/groups?selm=34A04430.CF9@ohioee.com

Why doesn't closing sys.stdout (stdin, stderr) really close it?

Python file objects are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`'s destructor, when `f` becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that's what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use `os.close()`:

```
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.

Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled Internet Protocols and Support and Internet Data Handling in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at https://wiki.python.org/moin/WebProgramming.

Cameron Laird maintains a useful set of pages about Python web technologies at https://web.archive.org/web/20210224183619/http://phaseit.net/claird/comp.lang.python/web_python.

How can I mimic CGI form submission (METHOD = POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses **`urllib.request`**:

```
#!/usr/local/bin/python

import urllib.request

# build the query string
qs = "First=Josephine&MI=Q&Last=Public"

# connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out
```

```
                                    '/cgi-bin/some-cgi-script',
with req:
    msg, hdrs = req.read(), req.info()
```

Note that in general for percent-encoded POST operations, query strings must be quoted using **urllib.parse.urlencode()**. For example, to send `name=Guy Steele, Jr.`:

```
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.'})
'name=Guy+Steele%2C+Jr.'
```

See also

HOWTO Fetch Internet Resources Using The urllib Package for extensive examples.

What module should I use to help with generating HTML?

You can find a collection of useful links on the Web Programming wiki page [https://wiki.python.org/moin/WebProgramming].

How do I send mail from a Python script?

Use the standard library module **smtplib**.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```
import sys, smtplib

fromaddr = input("From: ")
toaddrs  = input("To: ").split(',')
print("Enter message, end with ^D:")
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
```

```
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is `/usr/lib/sendmail`, sometimes `/usr/sbin/sendmail`. The sendmail manual page will help you out. Here's some sample code:

```
import os

SENDMAIL = "/usr/sbin/sendmail"  # sendmail location
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n")  # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)
```

How do I avoid blocking in the connect() method of a socket?

The **`select`** module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the **`socket.connect()`**, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the **`socket.connect_ex()`** method to avoid creating an exception. It will just return the errno value. To poll, you can call **`socket.connect_ex()`** again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to **`select.select()`** to check if it's writable.

Note

The **`asyncio`** module provides a general purpose single-threaded and concurrent asynchronous library, which can be used for writing non-blocking network code. The third-party Twisted [https://twistedmatrix.com/trac/] library is a popular and feature-rich alternative.

Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as **`DBM`** and **`GDBM`** are also included with standard Python. There is also the **`sqlite3`** module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the DatabaseProgramming wiki page [https://wiki.python.org/moin/DatabaseProgramming] for details.

How do you implement persistent objects in Python?

The **`pickle`** library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the **`shelve`** library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.

Mathematics and Numerics

How do I generate random numbers in Python?

The standard module **`random`** implements a random number generator. Usage is simple:

```
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses a random element from a given sequence.
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly.

There's also a `Random` class you can instantiate to create independent multiple random number generators.

  - How do I find undefined g++ symbols _builtin_new or _pure_virtual?
  - Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document Extending and Embedding the Python Interpreter.

Most intermediate or advanced Python books will also cover this topic.

Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.

Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

Cython [https://cython.org] and its relative Pyrex [https://www.cosc.canterbury.ac.nz/greg.ewing/python/Pyrex/] are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as SWIG [https://www.swig.org]. SIP [https://riverbankcomputing.com/software/sip/intro], CXX [https://cxx.sourceforge.net/] Boost [https://www.boost.org/libs/python/doc/index.html], or Weave [https://github.com/scipy/weave] are also alternatives for wrapping C++ libraries.

How can I execute arbitrary Python statements from C?

The highest-level function to do this is **PyRun_SimpleString()** which takes a single string argument to be executed in the context of the module `__main__` and returns `0` for success and `-1` when an exception occurred (including **SyntaxError**). If you want more control, use **PyRun_String()**; see the source for **PyRun_SimpleString()** in `Python/pythonrun.c`.

How can I evaluate an arbitrary Python expression from C?

Call the function **PyRun_String()** from the previous question with the start symbol **Py_eval_input**; it parses an expression, evaluates it and returns its value.

How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, **PyTuple_Size()** returns its length and **PyTuple_GetItem()** returns the item at a specified index. Lists have similar functions, **PyListSize()** and **PyList_GetItem()**.

For bytes, **PyBytes_Size()** returns its length and **PyBytes_AsStringAndSize()** provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C's **strlen()** should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use **PyBytes_Check()**, **PyTuple_Check()**, **PyList_Check()**, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like **PySequence_Length()**, **PySequence_GetItem()**, etc. as well as many other useful protocols such as numbers (**PyNumber_Index()** et al.) and mappings in the PyMapping APIs.

How do I use Py_BuildValue() to create a tuple of arbitrary length?

You can't. Use `PyTuple_Pack()` instead.

How do I call an object's method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *
PyObject_CallMethod(PyObject *object, const char *method
                    const char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`'ing the return value.

To call, e.g., a file object's "seek" method with arguments 10, 0 (assuming the file object pointer is "f"):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
        ... an exception occurred ...
}
else {
        Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` *always* wants a tuple for the argument list, to call a function without arguments, pass "()" for the format, and to call a function with one argument, surround the argument in parentheses, e.g. "(i)".

How do I catch the output from PyErr_Print() (or anything that prints to

stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to **`sys.stdout`** and **`sys.stderr`**. Call print_error, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the **`io.StringIO`** class:

```
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...     def __init__(self):
...         self.data = []
...     def write(self, stuff):
...         self.data.append(stuff)
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
foo
hello world!
```

How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in **`sys.modules`**), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in **`sys.modules`**.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling **`PyObject_SetAttrString()`** to assign to variables in the module also works.

How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading the "Extending and Embedding" document. Realize that for the Python run-time system, there isn't a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see Writing C is hard; are there any alternatives?.

I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)

How do I debug an extension?

When using GDB with dynamically loaded extensions, you can't set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish   # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```

I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don't include the `/usr/lib/python2.x/config/` directory, which contains various files required for compiling Python extensions.

For Red Hat, install the python-devel RPM to get the necessary files.

For Debian, run `apt-get install python-dev`.

How do I tell "incomplete input" from "invalid input"?

Sometimes you want to emulate the Python interactive interpreter's behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an "if" statement or you didn't close your parentheses or triple string quotes), but it gives

you a syntax error message immediately when the input is invalid.

In Python you can use the **codeop** module, which approximates the parser's behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call **PyRun_InteractiveLoop()** (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the **PyOS_ReadlineFunctionPointer()** to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., `g++ -shared -o mymodule.so mymodule.o`).

Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Yes, you can inherit from built-in classes such as **int**, **list**, **dict**, etc.

The Boost Python Library (BPL, https://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up *typing* Windows commands into what is referred to as a “Command prompt window”. Usually you can create such a window from your search bar by searching for `cmd`. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```

depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python *interpreter*. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “py” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `py` and hitting return:

```
C:\Users\YourName> py
```

You should then see something like:

```
Python 3.6.4 (v3.6.4:d48eceb, Dec 19 2017, 06:04:45) [MS
Type "help", "copyright", "credits" or "license" for mor
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
'HelloHelloHello'
```

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, call the `exit()` function or hold the `Ctrl` key down while you enter a `Z`, then hit the "`Enter`" key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as *Start ▸ Programs ▸ Python 3.x ▸ Python (command line)* that results in you seeing the `>>>` prompt in a new window. If so, the window will disappear after you call the `exit()` function or enter the `Ctrl-Z` character; Windows is running a single "python" command in the window, and closes it when you terminate the interpreter.

Now that we know the `py` command is recognized, you can give your Python script to it. You'll have to give either an absolute or a relative path to the Python script. Let's say your Python script is located in your desktop and is named `hello.py`, and your command prompt is nicely opened in your home directory so you're seeing something similar to:

```
C:\Users\YourName>
```

So now you'll ask the `py` command to give your script to Python by typing `py` followed by your script path:

```
C:\Users\YourName> py Desktop\hello.py
hello
```

How do I make Python scripts executable?

On Windows, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (`D:\Program Files\Python\python.exe "%1" %*`). This is enough to make scripts executable from the command prompt as 'foo.py'. If you'd rather be able to execute the script by simple typing 'foo' with no extension you need to add .py to the PATHEXT environment variable.

Why does Python sometimes take so long

to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.

How do I make an executable from a Python script?

See How can I create a stand-alone binary from a Python script? for a list of tools that can be used to make executables.

Is a `*.pyd` file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named `foo.pyd`, then it must have a function `PyInit_foo()`. You can then write Python "import foo", and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call `PyInit_foo()` to initialize it. You do not link your .exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.pyd is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say `import foo`. In a DLL,

linkage is declared in the source code with `__declspec(dllexport)`. In a .pyd, linkage is defined in a list of available functions.

How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do **not** build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `python`*NN*`.dll`; it is typically installed in `C:\Windows\System`. *NN* is the Python version, a number such as "33" for Python 3.3.

   You can link to Python in two different ways. Load-time linking means linking against `python`*NN*`.lib`, while run-time linking means linking against `python`*NN*`.dll`. (General note: `python`*NN*`.lib` is the so-called "import lib" corresponding to `python`*NN*`.dll`. It merely defines symbols for the linker.)

   Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `python`*NN*`.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `python`*NN*`.dll` (that is, Python's C API's) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

2. If you use SWIG, it is easy to create a Python "extension module" that will make the app's data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link *into* your .exe file (!) You do **not** have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

   The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```
#include <Python.h>
...
Py_Initialize();  // Initialize Python.
initmyAppc();  // Initialize (import) the helper cl
PyRun_SimpleString("import myApp");  // Import the
```

5. There are two problems with Python's C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

   Problem 1: The so-called "Very High Level" functions that take `FILE *` arguments will not work in a multi-compiler environment because each compiler's notion of a `struct FILE` will be different. From an implementation standpoint these are very low level functions.

   Problem 2: SWIG generates the following code when generating wrappers to void functions:

```
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

   Alas, Py_None is a macro that expands to a reference to a complex data structure called _Py_NoneStruct inside

pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```
return Py_BuildValue("");
```

It may be possible to use SWIG's `%typemap` command to make the change automatically, though I have not been able to get this to work (I'm a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app's windowing system. Rather, you (or the wxPythonWindow class) should create a "native" interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python's i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.

How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, **PEP 8** [https://peps.python.org/pep-0008/], recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take *Tools* ▸ *Options* ▸ *Tabs*, and for file type "Default" set "Tab size" and "Indent size" to 4, and select the "Insert spaces" radio button.

Python raises **`IndentationError`** or **`TabError`** if mixed tabs and spaces are causing problems in leading whitespace. You may also run the **`tabnanny`** module to check a directory tree in batch mode.

How do I check for a keypress without blocking?

Use the **msvcrt** module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.

How do I solve the missing api-ms-win-crt-runtime-l1-1-0.dll error?

This can occur on Python 3.5 and later when using Windows 8.1 or earlier without all updates having been installed. First ensure your operating system is supported and is up to date, and if that does not resolve the issue, visit the Microsoft support page [https://support.microsoft.com/en-us/help/3118401/] for guidance on manually installing the C Runtime update.

Graphic User Interface FAQ

Contents

- Graphic User Interface FAQ
  - General GUI Questions
  - What GUI toolkits exist for Python?
  - Tkinter questions
    - How do I freeze Tkinter applications?
    - Can I have Tk events handled while waiting for I/O?
    - I can't get key bindings to work in Tkinter: why?

General GUI Questions

What GUI toolkits exist for Python?

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called tkinter. This is probably the easiest to install (since it comes included with most binary distributions [https://www.python.org/downloads/] of Python) and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page [https://www.tcl.tk]. Tcl/Tk is fully portable to the macOS, Windows, and Unix platforms.

Depending on what platform(s) you are aiming at, there are also several alternatives. A list of cross-platform [https://wiki.python.org/moin/GuiProgramming#Cross-Platform_Frameworks] and platform-specific [https://wiki.python.org/moin/GuiProgramming#Platform-specific_Frameworks] GUI frameworks can be found on the python wiki.

Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the **`TCL_LIBRARY`** and **`TK_LIBRARY`** environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (https://tix.sourceforge.net/).

Build Tix with SAM enabled, perform the appropriate call to **`Tclsam_init()`**, etc. inside Python's `Modules/tkappinit.c`, and link with libtclsam and libtksam (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

On platforms other than Windows, yes, and you don't even need threads! But you'll have to restructure your I/O code a bit. Tk has the equivalent of Xt's **`XtAddInput()`** call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. See File Handlers.

I can't get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the **`bind()`** method don't get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn't have "keyboard focus". Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).

“Why is Python Installed on my Computer?” FAQ

What is Python?

Python is a programming language. It’s used for many different applications. It’s used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it’s also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner’s Guide to Python [https://wiki.python.org/moin/BeginnersGuide].

Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you’ll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq’s administrative tools are written in Python.
- Many Unix-compatible operating systems, such as macOS and some Linux distributions, have Python installed by default; it’s included in the base installation.

Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.

Glossary

>>>

The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

...

Can refer to:

- The default Python prompt of the interactive shell when entering the code for an indented code block, when within a pair of matching left and right delimiters (parentheses, square brackets, curly braces or triple quotes), or after specifying a decorator.
- The **`Ellipsis`** built-in constant.

2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as **`lib2to3`**; a standalone entry point is provided as `Tools/scripts/2to3`. See 2to3 — Automated Python 2 to 3 code translation.

abstract base class

Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like **`hasattr()`** would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by **`isinstance()`** and **`issubclass()`**; see the **`abc`** module documentation. Python comes with many built-

in ABCs for data structures (in the **collections.abc** module), numbers (in the **numbers** module), streams (in the **io** module), import finders and loaders (in the **importlib.abc** module). You can create your own ABCs with the **abc** module.

annotation

A label associated with a variable, a class attribute or a function parameter or return value, used by convention as a type hint.

Annotations of local variables cannot be accessed at runtime, but annotations of global variables, class attributes, and functions are stored in the **__annotations__** special attribute of modules, classes, and functions, respectively.

See variable annotation, function annotation, **PEP 484** [https://peps.python.org/pep-0484/] and **PEP 526** [https://peps.python.org/pep-0526/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

argument

A value passed to a function (or method) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to **complex()**:

  ```
  complex(real=3, imag=5)
  complex(**{'real': 3, 'imag': 5})
  ```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an iterable preceded by `*`. For example, `3` and `5` are both positional arguments in the following

calls:

```
complex(3, 5)
complex(*(3, 5))
```

Arguments are assigned to the named local variables in a function body. See the Calls section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the parameter glossary entry, the FAQ question on the difference between arguments and parameters, and **PEP 362** [https://peps.python.org/pep-0362/].

asynchronous context manager

An object which controls the environment seen in an **`async with`** statement by defining **`__aenter__()`** and **`__aexit__()`** methods. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

asynchronous generator

A function which returns an asynchronous generator iterator. It looks like a coroutine function defined with **`async def`** except that it contains **`yield`** expressions for producing a series of values usable in an **`async for`** loop.

Usually refers to an asynchronous generator function, but may refer to an *asynchronous generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain **`await`** expressions as well as **`async for`**, and **`async with`** statements.

asynchronous generator iterator

An object created by a asynchronous generator function.

This is an asynchronous iterator which when called using the

__anext__() method returns an awaitable object which will execute the body of the asynchronous generator function until the next **yield** expression.

Each **yield** temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *asynchronous generator iterator* effectively resumes with another awaitable returned by **__anext__()**, it picks up where it left off. See **PEP 492** [https://peps.python.org/pep-0492/] and **PEP 525** [https://peps.python.org/pep-0525/].

asynchronous iterable

An object, that can be used in an **async for** statement. Must return an asynchronous iterator from its **__aiter__()** method. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

asynchronous iterator

An object that implements the **__aiter__()** and **__anext__()** methods. `__anext__` must return an awaitable object. **async for** resolves the awaitables returned by an asynchronous iterator's **__anext__()** method until it raises a **StopAsyncIteration** exception. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

attribute

A value associated with an object which is usually referenced by name using dotted expressions. For example, if an object *o* has an attribute *a* it would be referenced as *o.a*.

It is possible to give an object an attribute whose name is not an identifier as defined by Identifiers and keywords, for example using **setattr()**, if the object allows it. Such an attribute will not be accessible using a dotted expression, and would instead need to be retrieved with **getattr()**.

awaitable

An object that can be used in an **await** expression. Can be a coroutine or an object with an **__await__()** method. See

also **PEP 492** [https://peps.python.org/pep-0492/].

BDFL

Benevolent Dictator For Life, a.k.a. Guido van Rossum [https://gvanrossum.github.io/], Python's creator.

binary file

A file object able to read and write bytes-like objects. Examples of binary files are files opened in binary mode (`'rb'`, `'wb'` or `'rb+'`), **`sys.stdin.buffer`**, **`sys.stdout.buffer`**, and instances of **`io.BytesIO`** and **`gzip.GzipFile`**.

See also text file for a file object able to read and write **`str`** objects.

borrowed reference

In Python's C API, a borrowed reference is a reference to an object. It does not modify the object reference count. It becomes a dangling pointer if the object is destroyed. For example, a garbage collection can remove the last strong reference to the object and so destroy it.

Calling **`Py_INCREF()`** on the borrowed reference is recommended to convert it to a strong reference in-place, except when the object cannot be destroyed before the last usage of the borrowed reference. The **`Py_NewRef()`** function can be used to create a new strong reference.

bytes-like object

An object that supports the Buffer Protocol and can export a C-contiguous buffer. This includes all **`bytes`**, **`bytearray`**, and **`array.array`** objects, as well as many common **`memoryview`** objects. Bytes-like objects can be used for various operations that work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as "read-write bytes-like

objects". Example mutable buffer objects include **bytearray** and a **memoryview** of a **bytearray**. Other operations require the binary data to be stored in immutable objects ("read-only bytes-like objects"); examples of these include **bytes** and a **memoryview** of a **bytes** object.

bytecode

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This "intermediate language" is said to run on a virtual machine that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for the dis module.

callable

A callable is an object that can be called, possibly with a set of arguments (see argument), with the following syntax:

```
callable(argument1, argument2, ...)
```

A function, and by extension a method, is a callable. An instance of a class that implements the **__call__()** method is also a callable.

callback

A subroutine function which is passed as an argument to be executed at some point in the future.

class

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

class variable

A variable defined in a class and intended to be modified only at class level (i.e., not in an instance of the class).

complex number

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of `-1`), often written `i` in mathematics or `j` in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a `j` suffix, e.g., `3+1j`. To get access to complex equivalents of the **`math`** module, use **`cmath`**. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

context manager

An object which controls the environment seen in a **`with`** statement by defining **`__enter__()`** and **`__exit__()`** methods. See **PEP 343** [https://peps.python.org/pep-0343/].

context variable

A variable which can have different values depending on its context. This is similar to Thread-Local Storage in which each execution thread may have a different value for a variable. However, with context variables, there may be several contexts in one execution thread and the main usage for context variables is to keep track of variables in concurrent asynchronous tasks. See **`contextvars`**.

contiguous

A buffer is considered contiguous exactly if it is either *C-contiguous* or *Fortran contiguous*. Zero-dimensional buffers are C and Fortran contiguous. In one-dimensional arrays, the items must be laid out in memory next to each other, in order of increasing indexes starting from zero. In multidimensional C-contiguous arrays, the last index varies the fastest when visiting items in order of memory address. However, in

Fortran contiguous arrays, the first index varies the fastest.

coroutine

Coroutines are a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the **`async def`** statement. See also **PEP 492** [https://peps.python.org/pep-0492/].

coroutine function

A function which returns a coroutine object. A coroutine function may be defined with the **`async def`** statement, and may contain **`await`**, **`async for`**, and **`async with`** keywords. These were introduced by **PEP 492** [https://peps.python.org/pep-0492/].

CPython

The canonical implementation of the Python programming language, as distributed on python.org [https://www.python.org]. The term "CPython" is used when necessary to distinguish this implementation from others such as Jython or IronPython.

decorator

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are **`classmethod()`** and **`staticmethod()`**.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(arg):
    ...
f = staticmethod(f)

@staticmethod
def f(arg):
```

. . .

The same concept exists for classes, but is less commonly used there. See the documentation for function definitions and class definitions for more about decorators.

descriptor

Any object which defines the methods **`__get__()`**, **`__set__()`**, or **`__delete__()`**. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using *a.b* to get, set or delete an attribute looks up the object named *b* in the class dictionary for *a*, but if *b* is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors' methods, see Implementing Descriptors or the Descriptor How To Guide.

dictionary

An associative array, where arbitrary keys are mapped to values. The keys can be any object with **`__hash__()`** and **`__eq__()`** methods. Called a hash in Perl.

dictionary comprehension

A compact way to process all or part of the elements in an iterable and return a dictionary with the results. `results = {n: n ** 2 for n in range(10)}` generates a dictionary containing key `n` mapped to value `n ** 2`. See Displays for lists, sets and dictionaries.

dictionary view

The objects returned from **`dict.keys()`**, **`dict.values()`**, and **`dict.items()`** are called dictionary views. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes. To force the dictionary view to become a full list use `list(dictview)`. See Dictionary

view objects.

docstring

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the **__doc__** attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

duck-typing

A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using **type()** or **isinstance()**. (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs **hasattr()** tests or EAFP programming.

EAFP

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many **try** and **except** statements. The technique contrasts with the LBYL style common to many other languages such as C.

expression

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as **while**. Assignments are also statements,

not expressions.

extension module

A module written in C or C++, using Python's C API to interact with the core and with user code.

f-string

String literals prefixed with `'f'` or `'F'` are commonly called "f-strings" which is short for formatted string literals. See also **PEP 498** [https://peps.python.org/pep-0498/].

file object

An object exposing a file-oriented API (with methods such as **`read()`** or **`write()`**) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called *file-like objects* or *streams*.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the **`io`** module. The canonical way to create a file object is by using the **`open()`** function.

file-like object

A synonym for file object.

filesystem encoding and error handler

Encoding and error handler used by Python to decode bytes from the operating system and encode Unicode to the operating system.

The filesystem encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions can raise **`UnicodeError`**.

The **`sys.getfilesystemencoding()`** and **`sys.getfilesystemencodeerrors()`** functions can be

used to get the filesystem encoding and error handler.

The filesystem encoding and error handler are configured at Python startup by the **`PyConfig_Read()`** function: see **`filesystem_encoding`** and **`filesystem_errors`** members of **`PyConfig`**.

See also the locale encoding.

finder

An object that tries to find the loader for a module that is being imported.

Since Python 3.3, there are two types of finder: meta path finders for use with **`sys.meta_path`**, and path entry finders for use with **`sys.path_hooks`**.

See **PEP 302** [https://peps.python.org/pep-0302/], **PEP 420** [https://peps.python.org/pep-0420/] and **PEP 451** [https://peps.python.org/pep-0451/] for much more detail.

floor division

Mathematical division that rounds down to nearest integer. The floor division operator is `//`. For example, the expression `11 // 4` evaluates to `2` in contrast to the `2.75` returned by float true division. Note that `(-11) // 4` is `-3` because that is `-2.75` rounded *downward*. See **PEP 238** [https://peps.python.org/pep-0238/].

function

A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also parameter, method, and the Function definitions section.

function annotation

An annotation of a function parameter or return value.

Function annotations are usually used for type hints: for example, this function is expected to take two **`int`**

arguments and is also expected to have an **`int`** return value:

```
def sum_two_numbers(a: int, b: int) -> int:
   return a + b
```

Function annotation syntax is explained in section Function definitions.

See variable annotation and **PEP 484** [https://peps.python.org/pep-0484/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

future

A future statement, `from __future__ import <feature>`, directs the compiler to compile the current module using syntax or semantics that will become standard in a future release of Python. The **`__future__`** module documents the possible values of *feature*. By importing this module and evaluating its variables, you can see when a new feature was first added to the language and when it will (or did) become the default:

```
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha',
```

garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles. The garbage collector can be controlled using the **`gc`** module.

generator

A function which returns a generator iterator. It looks like a normal function except that it contains **`yield`** expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the **`next()`** function.

Usually refers to a generator function, but may refer to a *generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

generator iterator

An object created by a generator function.

Each **`yield`** temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *generator iterator* resumes, it picks up where it left off (in contrast to functions which start fresh on every invocation).

generator expression

An expression that returns an iterator. It looks like a normal expression followed by a **`for`** clause defining a loop variable, range, and an optional **`if`** clause. The combined expression generates values for an enclosing function:

```
>>> sum(i*i for i in range(10))         # sum of sq
285
```

generic function

A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the single dispatch glossary entry, the **`functools.singledispatch()`** decorator, and **PEP 443** [https://peps.python.org/pep-0443/].

generic type

A type that can be parameterized; typically a container class such as **`list`** or **`dict`**. Used for type hints and annotations.

For more details, see generic alias types, **PEP 483** [https://peps.python.org/pep-0483/], **PEP 484** [https://peps.python.org/pep-0484/], **PEP 585** [https://peps.python.org/pep-0585/], and the

`typing` module.

GIL

See global interpreter lock.

global interpreter lock

The mechanism used by the CPython interpreter to assure that only one thread executes Python bytecode at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as `dict`) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

hash-based pyc

A bytecode cache file that uses the hash rather than the last-modified time of the corresponding source file to determine its validity. See Cached bytecode invalidation.

hashable

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a

set member, because these data structures use the hash value internally.

Most of Python's immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not; immutable containers (such as tuples and frozensets) are only hashable if their elements are hashable. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their **`id()`**.

IDLE

An Integrated Development and Learning Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

immutable

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

import path

A list of locations (or path entries) that are searched by the path based finder for modules to import. During import, this list of locations usually comes from **`sys.path`**, but for subpackages it may also come from the parent package's `__path__` attribute.

importing

The process by which Python code in one module is made available to Python code in another module.

importer

An object that both finds and loads a module; both a finder and loader object.

interactive

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

interpreted

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also interactive.

interpreter shutdown

When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the garbage collector. This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore (common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the `__main__` module or the script being run has finished executing.

iterable

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as **`list`**, **`str`**, and **`tuple`**) and some non-sequence types like **`dict`**, file objects, and objects of any classes you define with

an **`__iter__()`** method or with a **`__getitem__()`** method that implements sequence semantics.

Iterables can be used in a **`for`** loop and in many other places where a sequence is needed (**`zip()`**, **`map()`**, …). When an iterable object is passed as an argument to the built-in function **`iter()`**, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call **`iter()`** or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also iterator, sequence, and generator.

iterator

An object representing a stream of data. Repeated calls to the iterator's **`__next__()`** method (or passing it to the built-in function **`next()`**) return successive items in the stream. When no more data are available a **`StopIteration`** exception is raised instead. At this point, the iterator object is exhausted and any further calls to its **`__next__()`** method just raise **`StopIteration`** again. Iterators are required to have an **`__iter__()`** method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a **`list`**) produces a fresh new iterator each time you pass it to the **`iter()`** function or use it in a **`for`** loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in Iterator Types.

CPython implementation detail: CPython does not consistently apply the requirement that an iterator define **`__iter__()`**.

key function

A key function or collation function is a callable that returns

a value used for sorting or ordering. For example, **`locale.strxfrm()`** is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include **`min()`**, **`max()`**, **`sorted()`**, **`list.sort()`**, **`heapq.merge()`**, **`heapq.nsmallest()`**, **`heapq.nlargest()`**, and **`itertools.groupby()`**.

There are several ways to create a key function. For example. the **`str.lower()`** method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a **`lambda`** expression such as `lambda r: (r[0], r[2])`. Also, **`operator.attrgetter()`**, **`operator.itemgetter()`**, and **`operator.methodcaller()`** are three key function constructors. See the Sorting HOW TO for examples of how to create and use key functions.

keyword argument

See argument.

lambda

An anonymous inline function consisting of a single expression which is evaluated when the function is called. The syntax to create a lambda function is `lambda [parameters]: expression`

LBYL

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the EAFP approach and is characterized by the presence of many **`if`** statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes *key* from *mapping* after the test, but before the lookup. This

issue can be solved with locks or by using the EAFP approach.

locale encoding

On Unix, it is the encoding of the LC_CTYPE locale. It can be set with **`locale.setlocale(locale.LC_CTYPE, new_locale)`**.

On Windows, it is the ANSI code page (ex: `"cp1252"`).

On Android and VxWorks, Python uses `"utf-8"` as the locale encoding.

`locale.getencoding()` can be used to get the locale encoding.

See also the filesystem encoding and error handler.

list

A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements is O(1).

list comprehension

A compact way to process all or part of the elements in a sequence and return a list with the results. `result = ['{:#04x}'.format(x) for x in range(256) if x % 2 == 0]` generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The **`if`** clause is optional. If omitted, all elements in `range(256)` are processed.

loader

An object that loads a module. It must define a method named **`load_module()`**. A loader is typically returned by a finder. See **PEP 302** [https://peps.python.org/pep-0302/] for details and **`importlib.abc.Loader`** for an abstract base class.

magic method

An informal synonym for special method.

mapping

A container object that supports arbitrary key lookups and implements the methods specified in the **collections.abc.Mapping** or **collections.abc.MutableMapping** abstract base classes. Examples include **dict**, **collections.defaultdict**, **collections.OrderedDict** and **collections.Counter**.

meta path finder

A finder returned by a search of **sys.meta_path**. Meta path finders are related to, but different from path entry finders.

See **importlib.abc.MetaPathFinder** for the methods that meta path finders implement.

metaclass

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in Metaclasses.

method

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called `self`). See function and nested scope.

method resolution order

Method Resolution Order is the order in which base classes are searched for a member during lookup. See The Python 2.3

Method Resolution Order [https://www.python.org/download/releases/2.3/mro/] for details of the algorithm used by the Python interpreter since the 2.3 release.

module

An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of importing.

See also package.

module spec

A namespace containing the import-related information used to load a module. An instance of **`importlib.machinery.ModuleSpec`**.

MRO

See method resolution order.

mutable

Mutable objects can change their value but keep their **`id()`**. See also immutable.

named tuple

The term "named tuple" applies to any type or class that inherits from tuple and whose indexable elements are also accessible using named attributes. The type or class may have other features as well.

Several built-in types are named tuples, including the values returned by **`time.localtime()`** and **`os.stat()`**. Another example is **`sys.float_info`**:

```
>>> sys.float_info[1]                    # indexed a
1024
>>> sys.float_info.max_exp               # named fie
1024
>>> isinstance(sys.float_info, tuple)    # kind of t
```

```
True
```

Some named tuples are built-in types (such as the above examples). Alternatively, a named tuple can be created from a regular class definition that inherits from **`tuple`** and that defines named fields. Such a class can be written by hand or it can be created with the factory function **`collections.namedtuple()`**. The latter technique also adds some extra methods that may not be found in hand-written or built-in named tuples.

namespace

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions **`builtins.open`** and **`os.open()`** are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing **`random.seed()`** or **`itertools.islice()`** makes it clear that those functions are implemented by the **`random`** and **`itertools`** modules, respectively.

namespace package

A **PEP 420** [https://peps.python.org/pep-0420/] package which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no `__init__.py` file.

See also module.

nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the

innermost scope. Likewise, global variables read and write to the global namespace. The **`nonlocal`** allows writing to outer scopes.

new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like **`__slots__`**, descriptors, properties, **`__getattribute__()`**, class methods, and static methods.

object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any new-style class.

package

A Python module which can contain submodules or recursively, subpackages. Technically, a package is a Python module with a `__path__` attribute.

See also regular package and namespace package.

parameter

A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- *positional-or-keyword*: specifies an argument that can be passed either positionally or as a keyword argument. This is the default kind of parameter, for example *foo* and *bar* in the following:

  ```
  def func(foo, bar=None): ...
  ```

- *positional-only*: specifies an argument that can be supplied only by position. Positional-only parameters can be defined by including a `/` character in the parameter list of the function definition after them, for example *posonly1* and *posonly2* in the following:

```
def func(posonly1, posonly2, /, positional_or_k
```

- *keyword-only*: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare `*` in the parameter list of the function definition before them, for example *kw_only1* and *kw_only2* in the following:

  ```
  def func(arg, *, kw_only1, kw_only2): ...
  ```

- *var-positional*: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example *args* in the following:

  ```
  def func(*args, **kwargs): ...
  ```

- *var-keyword*: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example *kwargs* in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the **`inspect.Parameter`** class, the Function definitions section, and **PEP 362** [https://peps.python.org/pep-0362/].

path entry

A single location on the import path which the path based finder consults to find modules for importing.

path entry finder

A finder returned by a callable on **`sys.path_hooks`** (i.e. a

path entry hook) which knows how to locate modules given a path entry.

See **importlib.abc.PathEntryFinder** for the methods that path entry finders implement.

path entry hook

A callable on the **sys.path_hook** list which returns a path entry finder if it knows how to find modules on a specific path entry.

path based finder

One of the default meta path finders which searches an import path for modules.

path-like object

An object representing a file system path. A path-like object is either a **str** or **bytes** object representing a path, or an object implementing the **os.PathLike** protocol. An object that supports the **os.PathLike** protocol can be converted to a **str** or **bytes** file system path by calling the **os.fspath()** function; **os.fsdecode()** and **os.fsencode()** can be used to guarantee a **str** or **bytes** result instead, respectively. Introduced by **PEP 519** [https://peps.python.org/pep-0519/].

PEP

Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python or its processes or environment. PEPs should provide a concise technical specification and a rationale for proposed features.

PEPs are intended to be the primary mechanisms for proposing major new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

See **PEP 1** [https://peps.python.org/pep-0001/].

portion

A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in **PEP 420** [https://peps.python.org/pep-0420/].

positional argument

See argument.

provisional API

A provisional API is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a "solution of last resort" - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See **PEP 411** [https://peps.python.org/pep-0411/] for more details.

provisional package

See provisional API.

Python 3000

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated "Py3k".

Pythonic

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don't have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```
for piece in food:
    print(piece)
```

qualified name

A dotted name showing the "path" from a module's global scope to a class, function or method defined in that module, as defined in **PEP 3155** [https://peps.python.org/pep-3155/]. For top-level functions and classes, the qualified name is the same as the object's name:

```
>>> class C:
...     class D:
...         def meth(self):
...             pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

reference count

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. Programmers can call the **`sys.getrefcount()`** function to return the reference count for a particular object.

regular package

A traditional package, such as a directory containing an `__init__.py` file.

See also namespace package.

slots

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence

An iterable which supports efficient element access using integer indices via the **`__getitem__()`** special method and defines a **`__len__()`** method that returns the length of the sequence. Some built-in sequence types are **`list`**, **`str`**, **`tuple`**, and **`bytes`**. Note that **`dict`** also supports **`__getitem__()`** and **`__len__()`**, but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

The **`collections.abc.Sequence`** abstract base class defines a much richer interface that goes beyond just **`__getitem__()`** and **`__len__()`**, adding **`count()`**, **`index()`**, **`__contains__()`**, and **`__reversed__()`**.

Types that implement this expanded interface can be registered explicitly using `register()`.

set comprehension

A compact way to process all or part of the elements in an iterable and return a set with the results. `results = {c for c in 'abracadabra' if c not in 'abc'}` generates the set of strings `{'r', 'd'}`. See Displays for lists, sets and dictionaries.

single dispatch

A form of generic function dispatch where the implementation is chosen based on the type of a single argument.

slice

An object usually containing a portion of a sequence. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses `slice` objects internally.

special method

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in Special method names.

statement

A statement is part of a suite (a “block” of code). A statement is either an expression or one of several constructs with a keyword, such as `if`, `while` or `for`.

strong reference

In Python’s C API, a strong reference is a reference to an object which increments the object’s reference count when it is created and decrements the object’s reference count when it is deleted.

The **Py_NewRef()** function can be used to create a strong reference to an object. Usually, the **Py_DECREF()** function must be called on the strong reference before exiting the scope of the strong reference, to avoid leaking one reference.

See also borrowed reference.

text encoding

A string in Python is a sequence of Unicode code points (in range `U+0000–U+10FFFF`). To store or transfer a string, it needs to be serialized as a sequence of bytes.

Serializing a string into a sequence of bytes is known as "encoding", and recreating the string from the sequence of bytes is known as "decoding".

There are a variety of different text serialization codecs, which are collectively referred to as "text encodings".

text file

A file object able to read and write **str** objects. Often, a text file actually accesses a byte-oriented datastream and handles the text encoding automatically. Examples of text files are files opened in text mode (`'r'` or `'w'`), **sys.stdin**, **sys.stdout**, and instances of **io.StringIO**.

See also binary file for a file object able to read and write bytes-like objects.

triple-quoted string

A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

type

The type of a Python object determines what kind of object it is; every object has a type. An object's type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

type alias

A synonym for a type, created by assigning the type to an identifier.

Type aliases are useful for simplifying type hints. For example:

```
def remove_gray_shades(
        colors: list[tuple[int, int, int]]) -> list
    pass
```

could be made more readable like this:

```
Color = tuple[int, int, int]

def remove_gray_shades(colors: list[Color]) -> list
    pass
```

See `typing` and PEP 484 [https://peps.python.org/pep-0484/], which describe this functionality.

type hint

An annotation that specifies the expected type for a variable, a class attribute, or a function parameter or return value.

Type hints are optional and are not enforced by Python but they are useful to static type analysis tools, and aid IDEs with code completion and refactoring.

Type hints of global variables, class attributes, and functions, but not local variables, can be accessed using `typing.get_type_hints()`.

See `typing` and PEP 484 [https://peps.python.org/pep-0484/], which describe this functionality.

universal newlines

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention `'\n'`, the Windows convention `'\r\n'`, and the old Macintosh convention `'\r'`. See **PEP 278** [https://peps.python.org/pep-0278/] and **PEP 3116** [https://peps.python.org/pep-3116/], as well as **`bytes.splitlines()`** for an additional use.

variable annotation

An annotation of a variable or a class attribute.

When annotating a variable or a class attribute, assignment is optional:

```
class C:
    field: 'annotation'
```

Variable annotations are usually used for type hints: for example this variable is expected to take **`int`** values:

```
count: int = 0
```

Variable annotation syntax is explained in section Annotated assignment statements.

See function annotation, **PEP 484** [https://peps.python.org/pep-0484/] and **PEP 526** [https://peps.python.org/pep-0526/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

virtual environment

A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also **`venv`**.

virtual machine

A computer defined entirely in software. Python's virtual machine executes the bytecode emitted by the bytecode

compiler.

Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing "`import this`" at the interactive prompt.

About these documents

These documents are generated from reStructuredText [https://docutils.sourceforge.io/rst.html] sources by Sphinx [https://www.sphinx-doc.org/], a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the Dealing with Bugs page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils [https://docutils.sourceforge.io/] project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS [https://github.com/python/cpython/tree/3.11/Misc/ACKS] in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!

Dealing with Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

It can be sometimes faster to fix bugs yourself and contribute patches to Python as it streamlines the process and involves less people. Learn how to contribute.

Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the tracker. If you have a suggestion on how to fix it, include that as well.

If you're short on time, you can also email documentation bug reports to docs@python.org (behavioral bugs can be sent to python-list@python.org). 'docs@' is a mailing list run by volunteers; your request will be noticed, though it may take a while to be processed.

Documentation bugs **[https://github.com/python/cpython/issues?q=is%3Aissue+is%3Aopen+label%3Adocs]**
: A list of documentation bugs that have been submitted to the Python issue tracker.

Issue Tracking **[https://devguide.python.org/tracker/]**
: Overview of the process involved in reporting an improvement on the tracker.

Helping with Documentation **[https://devguide.python.org/docquality/#helping-with-documentation]**
: Comprehensive guide for individuals that are interested in

contributing to Python documentation.

Documentation Translations **[https://devguide.python.org/documenting/#translating]**
: A list of GitHub pages for documentation translation and their primary contacts.

Using the Python issue tracker

Issue reports for Python itself should be submitted via the GitHub issues tracker (https://github.com/python/cpython/issues). The GitHub issues tracker offers a web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers' time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the tracker using the search box at the top of the page.

If the problem you're reporting is not already in the list, log in to GitHub. If you don't already have a GitHub account, create a new account using the "Sign up" link. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit an issue. Click on the "New issue" button in the top bar to report a new issue.

The submission form has two fields, "Title" and "Comment".

For the "Title" field, enter a *very* short description of the problem; less than ten words is good.

In the "Comment" field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each issue report will be reviewed by a developer who will determine what needs to be done to correct the problem. You will receive an update each time an action is taken on the issue.

See also

How to Report Bugs Effectively **[https://www.chiark.greenend.org.uk/~sgtatham/bugs.html]**
: Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

Bug Writing Guidelines **[https://bugzilla.mozilla.org/page.cgi?id=bug-writing.html]**
: Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.

Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the Python Developer's Guide [https://devguide.python.org/]. If you have questions, the core-mentorship mailing list [https://mail.python.org/mailman3/lists/core-mentorship.python.org/] is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

History and License

History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see https://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see https://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see https://www.zope.org/). In 2001, the Python Software Foundation (PSF, see https://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see https://opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

2.6.1	1.6.1
2.6.1	2.0.1
2.6.2	
2.6.3	
2.6.1 and above	

Note

GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

Terms and conditions for accessing or otherwise using Python

Python software and documentation are licensed under the PSF License Agreement.

Starting with Python 3.8.6, examples, recipes, and other code in the documentation are dual licensed under the PSF License Agreement and the Zero-Clause BSD license.

Some software incorporated into Python is under different licenses. The licenses are listed with code falling under that license. See Licenses and Acknowledgements for Incorporated Software for an incomplete list of these licenses.

Distributing Python Modules
The up to date module distribution documentations

Note

The entire `distutils` package has been deprecated and will be removed in Python 3.12. This documentation is retained as a reference only, and will be removed with the package. See the What's New entry for more information.

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

Note

This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure

alternatives. Refer to the quick recommendations section [https://packaging.python.org/guides/tool-recommendations/] in the Python Packaging User Guide for more information.

This document describes the Python Distribution Utilities ("Distutils") from the module developer's point of view, describing the underlying capabilities that `setuptools` builds on to allow Python developers to make Python modules and extensions readily available to a wider audience.

- 9.42. **distutils.command.install_scripts** — Install script files from a package
- 9.43. **distutils.command.register** — Register a module with the Python Package Index
- 9.44. **distutils.command.check** — Check the meta-data of a package

1. An Introduction to Distutils

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the Installing Python Modules (Legacy version) chapter.

1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (`setup.py` by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus,

users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.

1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called **`foo`**, contained in a file `foo.py`, then your setup script can be as simple as this:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
      )
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the **`setup()`** function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section Writing the Setup Script for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run this command from a terminal:

```
python setup.py sdist
```

For Windows, open a command prompt window (*Start* ▸ *Accessories*) and change the command to:

```
setup.py sdist
```

sdist will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your **`foo`** module, all they have to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils *commands* they use: the **sdist** command is almost exclusively for module developers, while **install** is more often for installers (although most developers will want to install their own code occasionally).

Other useful built distribution formats are RPM, implemented by the **bdist_rpm** command, Solaris **pkgtool** (**bdist_pkgtool**), and HP-UX **swinstall** (**bdist_sdux**). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The **bdist_rpm** command uses the **rpm** executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time

by running

```
python setup.py bdist --help-formats
```

1.3. General Python terminology

If you're reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module
: the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module
: a module written in Python and contained in a single `.py` file (and possibly associated `.pyc` files). Sometimes referred to as a "pure module."

extension module
: a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (`.so`) file for Python extensions on Unix, a DLL (given the `.pyd` extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package
: a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file `__init__.py`.

root package
: the root of the hierarchy of packages. (This isn't really a package, since it doesn't have an `__init__.py` file. But we

have to call it something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in `sys.path` contributes modules to the root package.

1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution
: a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are NumPy, SciPy, Pillow, or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution
: a module distribution that contains only pure Python modules and packages. Sometimes referred to as a "pure distribution."

non-pure module distribution
: a module distribution that contains at least one extension module. Sometimes referred to as a "non-pure distribution."

distribution root
: the top-level directory of your source tree (or source distribution); the directory where `setup.py` exists. Generally `setup.py` will be run from this directory.

2. Writing the Setup Script

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section A Simple Example above, the setup script consists mainly of a call to **`setup()`**, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to **`setup()`**.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
```

```
      url='https://www.python.org/sigs/distutils-sig/',
      packages=['distutils', 'distutils.command'],
     )
```

There are only two differences between this and the trivial one-file distribution presented in section A Simple Example: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section Additional meta-data.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as **`glob.glob()`** or **`os.listdir()`** to specify files, you should be careful to write portable code instead of hardcoding path separators:

```
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```

2.1. Listing whole packages

The `packages` option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the `packages` list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package **`distutils`** is found in the directory `distutils` relative to the distribution root. Thus, when

you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyway.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the `package_dir` option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the "root package" (i.e., not in any package at all) are in `lib`, modules in the **`foo`** package are in `lib/foo`, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the **`foo`** package right in `lib`, the **`foo.bar`** package in `lib/bar`, etc. This would be written in the setup script as

```
package_dir = {'foo': 'lib'}
```

A `package: dir` entry in the `package_dir` dictionary implicitly applies to all packages below *package*, so the **`foo.bar`** case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although `package_dir` applies recursively, you must explicitly list all packages in `packages`: the Distutils will *not* recursively scan your source tree looking for any directory with an `__init__.py` file.)

2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the "root package" (i.e., no package at all). This simplest case was shown in section A Simple Example; here is a slightly more involved example:

```
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the "root" package, the other in the **pkg** package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.

2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to **setup()**, the `ext_modules` option. `ext_modules` is just a list of **Extension** instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called **foo** and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The **Extension** class can be imported from **distutils.core** along with **setup()**. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
      )
```

The **Extension** class (actually, the underlying extension-building machinery implemented by the **build_ext** command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.

2.3.1. Extension names and packages

The first argument to the **Extension** constructor is always the name of the extension, including any package names. For example,

```
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the **pkg** package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to **setup()**. For example,

```
setup(...,
      ext_package='pkg',
      ext_modules=[Extension('foo', ['foo.c']),
                   Extension('subpkg.bar', ['bar.c'])],
     )
```

will compile `foo.c` to the extension **pkg.foo**, and `bar.c` to **pkg.subpkg.bar**.

2.3.2. Extension source files

The second argument to the **Extension** constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (`.i`) files in the list; the **build_ext** command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

This warning notwithstanding, options to SWIG can be currently passed like this:

```
setup(...,
      ext_modules=[Extension('_foo', ['foo.i'],
                             swig_opts=['-modern', '-I..
      py_modules=['foo'],
     )
```

Or on the commandline like this:

```
> python setup.py build_ext --swig-opts="-modern -I../ir
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (`.mc`) files and resource definition (`.rc`) files for Visual C++. These will be compiled to binary resource (`.res`) files and linked into the executable.

2.3.3. Preprocessor options

Three optional arguments to **Extension** will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the

`include_dirs` option:

```
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```
Extension('foo', ['foo.c'], include_dirs=['/usr/include/
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils **install_headers** command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory—`/usr/local/include/python1.5` in this case—is always included in the search path when building Python extensions, the best approach is to write C code like

```
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils **`distutils.sysconfig`** module:

```
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1), '
setup(...,
      Extension(..., include_dirs=[incdir]),
      )
```

Even though this is quite portable—it will work on any Python installation, regardless of platform—it's probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of `(name, value)` tuples, where `name` is the name of the macro to define (a string) and `value` is its value: either a string or `None`. (Defining a macro `FOO` to `None` is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets `FOO` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
          define_macros=[('NDEBUG', '1'),
                         ('HAVE_STRFTIME', None)],
          undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```
Extension(...,
          libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```
Extension(...,
          library_dirs=['/usr/X11R6/lib'],
          libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

2.3.5. Other options

There are still some other options which can be used to handle special cases.

The `optional` option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The `extra_objects` option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

`extra_compile_args` and `extra_link_args` can be used to specify additional command line options for the respective compiler and linker command lines.

`export_symbols` is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `initmodule` to the list of exported symbols.

The `depends` option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.

2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.

2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the *requires* keyword argument to **`setup()`**. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include `'mymodule'` and `'xml.parsers.expat'`.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<       >       ==
<=      >=      !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:

Requires Expression	Explanation
`1.0`	Only version `1.0` is compatible
`>1.0, !=1.5.1, <2.0`	Any version after `1.0` and before `2.0` is compatible, except `1.5.1`

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the *provides* keyword argument to **`setup()`**. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

Provides Expression	Explanation
`mypkg`	Provide `mypkg`, using the distribution version
`mypkg (1.1)`	Provide `mypkg` version 1.1, regardless of the distribution version

A package can declare that it obsoletes other packages using the *obsoletes* keyword argument. The value for this is similar to that of the *requires* keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.

2.5. Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word "python", the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The **`--executable`** (or **`-e`**) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```
setup(...,
      scripts=['scripts/xmlproc_parse', 'scripts/xmlproc
      )
```

Changed in version 3.1: All the scripts will also be added to the `MANIFEST` file if no template is provided. See Specifying the files to distribute.

2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the **`setup()`** function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
    mypkg/
        __init__.py
        module.py
        data/
            tables.dat
            spoons.dat
            forks.dat
```

The corresponding call to **`setup()`** might be:

```
setup(...,
      packages=['mypkg'],
      package_dir={'mypkg': 'src/mypkg'},
      package_data={'mypkg': ['data/*.dat']},
      )
```

Changed in version 3.1: All the files that match `package_data` will be added to the `MANIFEST` file if no template is provided. See Specifying the files to distribute.

2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn't fit in the previous categories.

`data_files` specifies a sequence of (*directory*, *files*) pairs in the following way:

```
setup(...,
      data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']
                  ('config', ['cfg/data.cfg'])],
     )
```

Each (*directory*, *files*) pair in the sequence specifies the installation directory and the files to install there.

Each file name in *files* is interpreted relative to the `setup.py` script at the top of the package source distribution. Note that you can specify the directory where the data files will be installed, but you cannot rename the data files themselves.

The *directory* should be a relative path. It is interpreted relative to the installation prefix (Python's `sys.prefix` for system installations; `site.USER_BASE` for user installations). Distutils allows *directory* to be an absolute installation path, but this is discouraged since it is incompatible with the wheel packaging format. No directory information from *files* is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the **install** command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.

Changed in version 3.1: All the files that match `data_files` will be added to the `MANIFEST` file if no template is provided. See Specifying the files to distribute.

2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

Meta-Data	Description	Value	Notes
name	name of the package	short string	(1)
version	version of this release	short string	(1)(2)
author	package author's name	short string	(3)
author_email	email address of the package author	email address	(3)
maintainer	package maintainer's name	short string	(3)
maintainer_email	email address of the package maintainer	email address	(3)
url	home page for the package	URL	(1)
description	short, summary description of the package	short string	
long_description	longer description of the package	long string	
download_url	location where the package may be downloaded	URL	(4)
classifiers	a list of classifiers	list of strings	(4)
platforms	a list of platforms	list of strings	
keywords	list of keywords	list of strings	
provides	packages provided by the package	list of strings	
requires	packages required by the package	list of strings	
obsoletes	packages made obsolete by this package	list of strings	

Notes:

1. These fields are required.
2. It is recommended that versions take the form *major.minor[.patch[.sub]]*.
3. Either the author or the maintainer must be identified. If maintainer is provided, distutils lists it as the author in `PKG-INFO`.
4. The `long_description` field is used by PyPI when you

publish a package, to build its project page.

5. The `license` field is a text indicating the license covering the package where the license is not a selection from the "License" Trove classifiers. See the `Classifier` field. Notice that there's a `licence` distribution option which is deprecated but still acts as an alias for `license`.
6. This field must be a list.
7. The valid classifiers are listed on PyPI [https://pypi.org/classifiers].
8. To preserve backward compatibility, this field also accepts a string. If you pass a comma-separated string `'foo, bar'`, it will be converted to `['foo', 'bar']`, Otherwise, it will be converted to a list of one string.

'short string'
: A single line of text, not more than 200 characters.

'long string'
: Multiple lines of plain text in reStructuredText format (see http://docutils.sourceforge.net/).

'list of strings'
: See below.

Encoding the version information is an art in itself. Python packages generally adhere to the version format *major.minor[.patch][sub]*. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are "a1,a2,…,aN" (for alpha releases, where functionality and API may change), "b1,b2,…,bN" (for beta releases, which only fix bugs) and "pr1,pr2,…,prN" (for final pre-release release testing). Some examples:

0.1.0
: the first, experimental release of a package

1.0.1a2
: the second alpha release of the first patch version of 1.0

`classifiers` must be specified in a list:

```
setup(...,
      classifiers=[
          'Development Status :: 4 - Beta',
          'Environment :: Console',
          'Environment :: Web Environment',
          'Intended Audience :: End Users/Desktop',
          'Intended Audience :: Developers',
          'Intended Audience :: System Administrators',
          'License :: OSI Approved :: Python Software Fo
          'Operating System :: MacOS :: MacOS X',
          'Operating System :: Microsoft :: Windows',
          'Operating System :: POSIX',
          'Programming Language :: Python',
          'Topic :: Communications :: Email',
          'Topic :: Office/Business',
          'Topic :: Software Development :: Bug Tracking
          ],
      )
```

Changed in version 3.7: **setup** now warns when `classifiers`, `keywords` or `platforms` fields are not specified as a list or a string.

2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the **DISTUTILS_DEBUG** environment variable can be set to anything except an empty string, and distutils will now print detailed information about what it is doing, dump the full traceback when an exception occurs, and print the whole command line when an external program (like a C compiler) fails.

3. Writing the Setup Configuration File

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

Often, it's not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user's system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```

where *command* is one of the Distutils commands (e.g. **build_py**, **install**), and *option* is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a `'#'` character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal **`--help`** option, e.g.

```
$ python setup.py --help build_ext
[...]
Options for 'build_ext' command:
  --build-lib (-b)     directory for compiled extension
  --build-temp (-t)    directory for temporary files (bu
  --inplace (-i)       ignore build-lib and put compiled
                       source directory alongside your p
  --include-dirs (-I)  list of directories to search for
  --define (-D)        C preprocessor macros to define
  --undef (-U)         C preprocessor macros to undefine
  --swig-opts          list of SWIG command line options
[...]
```

Note that an option spelled **`--foo-bar`** on the command-line is spelled `foo_bar` in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension **`pkg.ext`**, and you want the compiled extension file (`ext.so` on Unix, say) to be put in the same source directory as your pure Python modules **`pkg.mod1`** and **`pkg.mod2`**. You can always use the **`--inplace`** option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the **build_ext** command explicitly, and remember to provide **`--inplace`**. An easier way is to "set and forget" this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify **build_ext**. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don't change from run to run; for example, **bdist_rpm** needs to know everything required to generate a "spec" file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to **bdist_rpm**, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils' own `setup.cfg`:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
            README.txt
            USAGE.txt
            doc/
            examples/
```

Note that the `doc_files` option is simply a whitespace-separated

string split across multiple lines for readability.

See also

Syntax of config files in “Installing Python Modules”
More information on the configuration files is available in the manual for system administrators.

Footnotes

[1] This ideal probably won’t be achieved until auto-configuration is fully supported by the Distutils.

4. Creating a Source Distribution

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

As shown in section A Simple Example, you use the **sdist** command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven't specified any **sdist** options in the setup script or config file), **sdist** creates the archive of the default format for the current platform. The default format is a gzip'ed tar file (`.tar.gz`) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the **`--formats`** option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

Format	Description	Notes
`zip`	ZIP file (`.zip`)	(1),(3)
`gztar`	gzip'ed tar file (`.tar.gz`)	(2),(4)
`bztar`	bzip2'ed tar file (`.tar.bz2`)	(2)
`xztar`	xz'ed tar file (`.tar.xz`)	(2)
`ztar`	compressed tar file (`.tar.Z`)	(2),(4)
`tar`	tar file (`.tar`)	(2)

Changed in version 3.5: Added support for the `xztar` format.

Notes:

1. default on Windows
2. default on Unix
3. requires either external **zip** utility or **`zipfile`** module (part of the standard Python library since Python 1.6)
4. requires the **compress** program. Notice that this format is now pending for deprecation and will be removed in the future versions of Python.
5. deprecated by PEP 527 [https://peps.python.org/pep-0527/]; PyPI [https://pypi.org] only accepts `.zip` and `.tar.gz` files.

When using any `tar` format (`gztar`, `bztar`, `xztar`, `ztar` or `tar`), under Unix you can specify the `owner` and `group` names that will be set for each member of the archive.

For example, if you want all files of the archive to be owned by root:

```
python setup.py sdist --owner=root --group=root
```

4.1. Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the **sdist** command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options
- scripts identified by the `scripts` option See Installing Scripts.
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)

- Any of the standard README files (`README`, `README.txt`, or `README.rst`), `setup.py` (or whatever you called your setup script), and `setup.cfg`.
- all files that matches the `package_data` metadata. See Installing Package Data.
- all files that matches the `data_files` metadata. See Installing Additional Files.

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a *manifest template*, called `MANIFEST.in` by default. The manifest template is just a list of instructions for how to generate your manifest file, `MANIFEST`, which is the exact list of files to include in your source distribution. The **sdist** command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own `MANIFEST`, you must specify everything: the default set of files described above does not apply in this case.

Changed in version 3.1: An existing generated `MANIFEST` will be regenerated without **sdist** comparing its modification time to the one of `MANIFEST.in` or `setup.py`.

Changed in version 3.1.3: `MANIFEST` files start with a comment indicating they are generated. Files without this comment are not overwritten or removed.

Changed in version 3.2.2: **sdist** will read a `MANIFEST` file if no `MANIFEST.in` exists, like it used to do.

Changed in version 3.7: `README.rst` is now included in the list of distutils standard READMEs.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching `*.txt`, all files anywhere under the `examples` directory matching `*.txt` or `*.py`, and exclude all directories matching `examples/sample?/build`. All of this is done *after* the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the **`--no-defaults`** option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section Creating a source distribution: the sdist command.

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils "build" tree (default `build/`)
- all files in directories named `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzr` or `_darcs`

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the **`--no-defaults`** option, and you can disable the standard exclude set with **`--no-prune`**.

Following the Distutils' own manifest template, let's trace how the **sdist** command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the `distutils` and `distutils/command` subdirectories (because packages corresponding to those two directories were mentioned in the `packages` option in the setup script—see section Writing the

Setup Script)
2. include `README.txt`, `setup.py`, and `setup.cfg` (standard files)
3. include `test/test*.py` (standard files)
4. include `*.txt` in the distribution root (this will find `README.txt` a second time, but such redundancies are weeded out later)
5. include anything matching `*.txt` or `*.py` in the sub-tree under `examples`,
6. exclude all files in the sub-trees starting at directories matching `examples/sample?/build`—this may exclude files included by the previous two steps, so it's important that the `prune` command in the manifest template comes after the `recursive-include` command
7. exclude the entire `build` tree, and any `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzr` and `_darcs` directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.

4.2. Manifest-related options

The normal course of operations for the **sdist** command is as follows:

- if the manifest file (`MANIFEST` by default) exists and the first line does not have a comment indicating it is generated from `MANIFEST.in`, then it is used as is, unaltered
- if the manifest file doesn't exist or has been previously automatically generated, read `MANIFEST.in` and create the manifest
- if neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set
- use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use

the **`--no-defaults`** and **`--no-prune`** to disable the standard "include" and "exclude" sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

`-o` is a shortcut for **`--manifest-only`**.

5. Creating Built Distributions

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called *packagers* springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be their own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager

uses the setup script and the **bdist** command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:

```
python setup.py bdist
```

then the Distutils builds my module distribution (the Distutils itself in this case), does a "fake" installation (also in the `build` directory), and creates the default type of built distribution for my platform. The default format for built distributions is a "dumb" tar file on Unix, and a simple executable installer on Windows. (That tar file is considered "dumb" because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates `Distutils-1.0.`*`plat`*`.tar.gz`; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run `python setup.py install`. (The "right place" is either the root of the filesystem or Python's *`prefix`* directory, depending on the options given to the **bdist_dumb** command; the default is to make dumb distributions relative to *`prefix`*.)

Obviously, for pure Python distributions, this isn't any simpler than just running `python setup.py install`—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating "smart" built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn't include any extensions.

The **bdist** command has a **`--formats`** option, similar to the **sdist** command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a Unix system, create

`Distutils-1.0.`*plat*`.zip`—again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

Format	Description	Notes
`gztar`	gzipped tar file (`.tar.gz`)	(1), (3)
`bztar`	bzipped tar file (`.tar.bz2`)	(3)
`xztar`	xzipped tar file (`.tar.xz`)	(3)
`ztar`	compressed tar file (`.tar.Z`)	(3), (4)
`tar`	tar file (`.tar`)	(3)
`zip`	zip file (`.zip`)	(2), (4)
`rpm`	RPM	(5)
`pkgtool`	Solaris **pkgtool**	
`sdux`	HP-UX **swinstall**	
`msi`	Microsoft Installer.	

Changed in version 3.5: Added support for the `xztar` format.

Notes:

1. default on Unix
2. default on Windows
3. requires external **compress** utility.
4. requires either external **zip** utility or **`zipfile`** module (part of the standard Python library since Python 1.6)
5. requires external **rpm** utility, version 3.0.4 or better (use `rpm --version` to find out which version you have)

You don't have to use the **bdist** command with the **`--formats`** option; you can also use the command that directly implements the format you're interested in. Some of these **bdist** "sub-commands" actually generate several similar formats; for instance, the **bdist_dumb** command generates all the "dumb" archive formats (`tar`, `gztar`, `bztar`, `xztar`, `ztar`, and `zip`), and **bdist_rpm** generates both binary and source RPMs. The **bdist** sub-commands, and the formats generated by each, are:

Command	Formats
bdist_dumb	gztar, bztar, xztar, ztar, zip
bdist_rpm	rpm, srpm

The following sections give details on the individual **bdist_*** commands.

5.1. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the **bdist_rpm** command:

```
python setup.py bdist_rpm
```

or the **bdist** command with the **--format** option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple **bdist_*** commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@exa
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the **bdist_rpm** command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:

RPM `.spec` file option or section	Distutils setup script option
Name	
Summary (in preamble)	

Version	`version`
Vendor	`author` and `author_email`, or — & `maintainer` and `maintainer_email`
Copyright	`license`
Url	`url`
%description (section)	`long_description`

Additionally, there are many options in `.spec` files that don't have corresponding options in the setup script. Most of these are handled through options to the **bdist_rpm** command as follows:

RPM .spec file option or section	**bdist_rpm** option
Release	`release`
Group	`group` (default: "Development/Libraries")
Vendor	`vendor` (default: "(none)")
Packager	`packager` (default: "(none)")
Provides	`provides` (default: "(none)")
Requires	`requires` (default: "(none)")
Conflicts	`conflicts` (default: "(none)")
Obsoletes	`obsoletes` (default: "(none)")
Distribution	`distribution_name` (default: "(none)")
BuildRequires	`build_requires` (default: "(none)")

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it's usually best to put them in the setup configuration file, `setup.cfg`—see section Writing the Setup Configuration File. If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/.pydistutils.cfg`). If you want to temporarily disable this file, you can pass the **`--no-user-cfg`** option to `setup.py`.

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the "binary" RPM (which may or may not contain

binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the **--spec-only** option to make **bdist_rpm** just create the `.spec` file and exit; in this case, the `.spec` file will be written to the "distribution directory"—normally `dist/`, but customizable with the **--dist-dir** option. (Normally, the `.spec` file winds up deep in the "build tree," in a temporary directory created by **bdist_rpm**.)

5.2. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the **--plat-name** option to the build command. Valid values are currently 'win32', and 'win-amd64'. For example, on a 32bit version of Windows, you could execute:

```
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension.

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targeting - it is not possible from a binary installation of Python (as the .lib etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the `PCbuild/PCbuild.sln` solution in the Python source tree and build the "x64" configuration of the 'pythoncore' project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel-> [Add/ Remove] Programs is a convenient way to check or modify your existing install.)

5.2.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the **`--install-script`** option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to **`-install`**, and again at uninstallation time before the files are removed with `argv[1]` set to **`-remove`**.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

directory_created(*path*)

file_created(*path*)

> These functions should be called when a directory or file is created by the postinstall script at installation time. It will register *path* with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

get_special_folder_path(*csidl_string*)

> This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. *csidl_string* must be one of the following strings:

```
"CSIDL_APPDATA"

"CSIDL_COMMON_STARTMENU"
"CSIDL_STARTMENU"

"CSIDL_COMMON_DESKTOPDIRECTORY"
"CSIDL_DESKTOPDIRECTORY"

"CSIDL_COMMON_STARTUP"
"CSIDL_STARTUP"

"CSIDL_COMMON_PROGRAMS"
"CSIDL_PROGRAMS"

"CSIDL_FONTS"
```

If the folder cannot be retrieved, **OSError** is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the **SHGetSpecialFolderPath()** function.

create_shortcut(*target*, *description*, *filename*[, *arguments*[, *workdir*[, *iconpath*[, *iconindex*]]]])

This function creates a shortcut. *target* is the path to the program to be started by the shortcut. *description* is the description of the shortcut. *filename* is the title of the shortcut that the user will see. *arguments* specifies the command line arguments, if any. *workdir* is the working directory for the program. *iconpath* is the file containing the icon for the shortcut, and *iconindex* is the index of the icon in the file *iconpath*. Again, for details consult the Microsoft documentation for the **IShellLink** interface.

6. Distutils Examples

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also

Distutils Cookbook [https://wiki.python.org/moin/Distutils/Cookbook]
: Collection of recipes showing how to achieve more control over distutils.

6.1. Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
        setup.py
        foo.py
```

(In all diagrams in this section, *<root>* will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
      )
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules **`foo`** and **`bar`**, your setup might look like this:

```
<root>/
        setup.py
        foo.py
        bar.py
```

and the setup script might be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      py_modules=['foo', 'bar'],
      )
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.

6.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an `__init__.py` file).

The setup script from the last example could also be written as

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=[''],
      )
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
        setup.py
        src/      foo.py
                  bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'': 'src'},
      packages=[''],
      )
```

More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the **`foo`** and **`bar`** modules belong in package **`foobar`**, one way to layout your source tree is

```
<root>/
        setup.py
        foobar/
                __init__.py
                foo.py
                bar.py
```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar'],
      )
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the **`foobar`** package:

```
<root>/
        setup.py
        src/
                __init__.py
                foo.py
                bar.py
```

an appropriate setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
      )
```

Or, you might put modules from your main package right in the distribution root:

```
<root>/
        setup.py
        __init__.py
        foo.py
        bar.py
```

in which case your setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
      )
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does *not* scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```
<root>/
        setup.py
        foobar/
                __init__.py
                foo.py
                bar.py
                subfoo/
                        __init__.py
                        blah.py
```

then the corresponding setup script would be

```
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar', 'foobar.subfoo'],
```

```
      )
```

6.3. Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
        setup.py
        foo.c
```

If the **`foo`** extension belongs in the root package, the setup script for this could be

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
      )
```

If the extension actually belongs in a package, say **`foopkg`**, then

With exactly the same source tree layout, this extension can be put in the **`foopkg`** package simply by changing the name of the extension:

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
      version='1.0',
      ext_modules=[Extension('foopkg.foo', ['foo.c'])],
      )
```

6.4. Checking a package

The `check` command allows you to verify if your package meta-

data meet the minimum requirements to build a distribution.

To run it, just call it using your `setup.py` script. If something is missing, `check` will display a warning.

Let's take an example with a simple script:

```
from distutils.core import setup

setup(name='foobar')
```

Running the `check` command will display some warnings:

```
$ python setup.py check
running check
warning: check: missing required meta-data: version, url
warning: check: missing meta-data: either (author and au
         (maintainer and maintainer_email) should be sup
```

If you use the reStructuredText syntax in the `long_description` field and docutils [http://docutils.sourceforge.net] is installed you can check if the syntax is fine with the `check` command, using the `restructuredtext` option.

For example, if the `setup.py` script is changed like this:

```
from distutils.core import setup

desc = """\
My description
==============

This is the description of the ``foobar`` package.
"""

setup(name='foobar', version='1', author='tarek',
    author_email='tarek@ziade.org',
    url='http://example.com', long_description=desc)
```

Where the long description is broken, `check` will be able to detect it by using the **`docutils`** parser:

```
$ python setup.py check --restructuredtext
running check
warning: check: Title underline too short. (line 2)
warning: check: Could not finish the parsing.
```

6.5. Reading the metadata

The **distutils.core.setup()** function provides a command-line interface that allows you to query the metadata fields of a project through the `setup.py` script of a given project:

```
$ python setup.py --name
distribute
```

This call reads the `name` metadata by running the **distutils.core.setup()** function. Although, when a source or binary distribution is created with Distutils, the metadata fields are written in a static file called `PKG-INFO`. When a Distutils-based project is installed in Python, the `PKG-INFO` file is copied alongside the modules and packages of the distribution under `NAME-VERSION-pyX.X.egg-info`, where `NAME` is the name of the project, `VERSION` its version as defined in the Metadata, and `pyX.X` the major and minor version of Python like `2.7` or `3.2`.

You can read back this static file, by using the **distutils.dist.DistributionMetadata** class and its **read_pkg_file()** method:

```
>>> from distutils.dist import DistributionMetadata
>>> metadata = DistributionMetadata()
>>> metadata.read_pkg_file(open('distribute-0.6.8-py2.7.
>>> metadata.name
'distribute'
>>> metadata.version
'0.6.8'
>>> metadata.description
'Easily download, build, install, upgrade, and uninstall
```

Notice that the class can also be instantiated with a metadata file path to loads its values:

```
>>> pkg_info_path = 'distribute-0.6.8-py2.7.egg-info'
>>> DistributionMetadata(pkg_info_path).name
'distribute'
```

7. Extending Distutils

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the **`distutils.cmd.Command`** class. New commands may directly inherit from **`Command`**, while replacements often derive from **`Command`** indirectly, directly subclassing the command they are replacing. Commands are required to derive from **`Command`**.

7.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your `setup.py` script, and cause the **`distutils.core.setup()`** function use them:

```
from distutils.command.build_py import build_py as _buil
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

    # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
      ...)
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing `setup.py` scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration option, `command_packages` (command-line option **`--command-packages`**), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not

specified, the search is only performed in the **distutils.command** package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages **distutils.command**, **distcmds**, and **buildcmds** will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command **bdist_openpkg** could be implemented by the class **distcmds.bdist_openpkg.bdist_openpkg** or **buildcmds.bdist_openpkg.bdist_openpkg**.

7.2. Adding new distribution types

Commands that create distributions (files in the `dist/` directory) need to add `(command, filename)` pairs to `self.distribution.dist_files` so that **upload** can upload it to PyPI. The *filename* in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.

8. Command Reference

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

8.1. Installing modules: the install command family

The install command ensures that the build commands have been run and then runs the subcommands **install_lib**, **install_data** and **install_scripts**.

8.1.1. install_data

This command installs all data files provided with the distribution.

8.1.2. install_scripts

This command installs all (Python) scripts in the distribution.

8.2. Creating a source distribution: the sdist command

The manifest template commands are:

Command	Description
include *pat1 pat2 ...*	include all files matching any of the listed patterns
exclude *pat1 pat2 ...*	exclude all files matching any of the listed patterns
recursive-include *dir pat1 pat2 ...*	include all files under *dir* matching any of the listed patterns

recursive-exclude *dir pat1 pat2 ...*	exclude all files under *dir* matching any of the listed patterns
global-include *pat1 pat2 ...*	include all files anywhere in the source tree matching — & any of the listed patterns
global-exclude *pat1 pat2 ...*	exclude all files anywhere in the source tree matching — & any of the listed patterns
prune *dir*	exclude all files under *dir*
graft *dir*	include all files under *dir*

The patterns here are Unix-style “glob” patterns: `*` matches any sequence of regular filename characters, `?` matches any single regular filename character, and `[range]` matches any of the characters in *range* (e.g., `a-z`, `a-zA-Z`, `a-f0-9_.`). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.

9. API Reference

See also

New and changed setup.py arguments in setuptools [https://web.archive.org/web/20210614192516/https://setuptools.pypa.io/en/stable/userguide/keywords.html]

The `setuptools` project adds new capabilities to the `setup` function and other APIs, makes the API consistent across different Python versions, and is hence recommended over using `distutils` directly.

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

9.1. `distutils.core` — Core Distutils functionality

The **`distutils.core`** module is the only module that needs to be installed to use the Distutils. It provides the **`setup()`** (which is called from the setup script). Indirectly provides the **`distutils.dist.Distribution`** and **`distutils.cmd.Command`** class.

distutils.core.setup(*arguments*)

The basic do-everything function that does most everything you could ever ask for from a Distutils method.

The setup function takes a large number of arguments. These

are laid out in the following table.

argument name	value type	value
name	string	the name of the package
version	string	the version number of the package; see **distutils.version**
description	string	a single line describing the package
long_description	string	longer description of the package
author	string	the name of the package author
author_email	string	the email address of the package author
maintainer	string	the name of the current maintainer, if different from the author. Note that if the maintainer is provided, distutils will use it as the author in PKG-INFO
maintainer_email	string	the email address of the current maintainer, if different from the author
url	string	a URL for the package (homepage)
download_url	string	a URL to download the package
packages	list of strings	a list of Python packages that distutils will manipulate
py_modules	list of strings	a list of Python modules that distutils will manipulate
scripts	list of strings	a list of standalone script files to be built and installed
ext_modules	list of Extension	a list of Python extensions to be built
classifiers	list of strings	a list of categories for the package; see **distutils.core.Extension** and PyPI.
distclass	a subclass of **distutils.core.Distribution**	the Distribution class to use
script_name	string	the name of the setup.py script - defaults to sys.argv[0]
script_args	list of strings	arguments to supply to the setup script
options	dictionary	default options for the setup script
license	string	the license for the package
keywords	list of strings or string	descriptive meta-data, see PEP 314
platforms	list of strings or string	a list of platforms
cmdclass	dictionary	a mapping of command names to **Command** subclasses
data_files	list of tuples	a list of data files to install
package_dir	dictionary	a mapping of package to directory names

distutils.core.run_setup(*script_name*[, *script_args*=*None*, *stop_after*=*'run'*])

Run a setup script in a somewhat controlled environment, and return the **distutils.dist.Distribution** instance that drives things. This is useful if you need to find out the

distribution meta-data (passed as keyword args from *script* to **setup()**), or the contents of the config files or command-line.

script_name is a file that will be read and run with **exec()**. `sys.argv[0]` will be replaced with *script* for the duration of the call. *script_args* is a list of strings; if supplied, `sys.argv[1:]` will be replaced by *script_args* for the duration of the call.

stop_after tells **setup()** when to stop processing; possible values:

value	description
init	Stop after the **Distribution** instance has been created and populated with the keyword arguments to **setup()**
config	Stop after config files have been parsed (and their data stored in the **Distribution** instance)
commandline	Stop after the command-line (`sys.argv[1:]` or *script_args*) have been parsed (and the data stored in the **Distribution** instance.)
run	Stop after all commands have been run (the same as if **setup()** had been called in the usual way). This is the default value.

In addition, the **distutils.core** module exposed a number of classes that live elsewhere.

- **Extension** from **distutils.extension**
- **Command** from **distutils.cmd**
- **Distribution** from **distutils.dist**

A short description of each of these follows, but see the relevant module for the full reference.

class distutils.core.Extension

The Extension class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:

argument name	value

name string
the full name of the extension, including any packages — ie. *not* a filename or pathname, but Python dotted name

sources list of strings
list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the **build_ext** command as source for a Python extension.

include_dirs list of strings
list of directories to search for C/C++ header files (in Unix form for portability)

define_macros list of tuples
list of macros to define; each macro is defined using a 2-tuple `(name, value)`, where *value* is either the string to define it to or `None` to define it without a particular value (equivalent of `#define FOO` in source or **`-DFOO`** on Unix C compiler command line)

undef_macros list of strings
list of macros to undefine explicitly

library_dirs list of strings
list of directories to search for C/C++ libraries at link time

libraries list of strings
list of library names (not filenames or paths) to link against

runtime_library_dirs list of strings
list of directories to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)

extra_objects list of strings
list of extra files to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

extra_compile_args list of strings
any extra platform- and compiler-specific information to use when compiling the source files in 'sources'. For platforms and compilers where a command line makes sense, this is typically a list of command-line arguments, but for other platforms it could be anything.

extra_link_args list of strings
any extra platform- and compiler-specific information to use when linking object files together to create the extension (or to create a new static Python interpreter). Similar interpretation as for 'extra_compile_args'.

export_symbols list of strings
list of symbols to be exported from a shared extension. Not used on all platforms, and not generally necessary for Python extensions, which typically export exactly one symbol: `init` + extension_name.

depends list of strings
list of files that the extension depends on

language
extension language (i.e. `'c'`, `'c++'`, `'objc'`). Will be

detected from the source extensions if not provided.

optional that a build failure in the extension should not abort the build process, but simply skip the extension.

Changed in version 3.8: On Unix, C extensions are no longer linked to libpython except on Android and Cygwin.

class distutils.core.Distribution

A `Distribution` describes how to build, install and package up a Python software package.

See the `setup()` function for a list of keyword arguments accepted by the Distribution constructor. `setup()` creates a Distribution instance.

Changed in version 3.7: `Distribution` now warns if `classifiers`, `keywords` and `platforms` fields are not specified as a list or a string.

class distutils.core.Command

A `Command` class (or rather, an instance of one of its subclasses) implement a single distutils command.

9.2. `distutils.ccompiler` — CCompiler base class

This module provides the abstract base class for the `CCompiler` classes. A `CCompiler` instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

distutils.ccompiler.gen_lib_options(*compiler*, *library_dirs*, *runtime_library_dirs*, *libraries*)

Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library_dirs* are,

respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

distutils.ccompiler.gen_preprocess_options(*macros*, *include_dirs*)

Generate C pre-processor options (**-D**, **-U**, **-I**) as used by at least two types of compilers: the typical Unix compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where `(name,)` means undefine (**-U**) macro *name*, and `(name, value)` means define (**-D**) macro *name* to *value*. *include_dirs* is just a list of directory names to be added to the header file search path (**-I**). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

distutils.ccompiler.get_default_compiler(*osname*, *platform*)

Determine the default compiler to use for the given platform.

osname should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and *platform* the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

distutils.ccompiler.new_compiler(*plat=None*, *compiler=None*, *verbose=0*, *dry_run=0*, *force=0*)

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. *plat* defaults to `os.name` (eg. `'posix'`, `'nt'`), and *compiler* defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are "traditional Unix interface" (**UnixCCompiler** class) and Visual C++ (**MSVCCompiler** class). Note that it's perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for *compiler*, *plat* is ignored.

distutils.ccompiler.show_compilers()

Print list of available compilers (used by the **--help-compiler** options to **build**, **build_ext**, **build_clib**).

class distutils.ccompiler.CCompiler([*verbose*=*0*, *dry_run*=*0*, *force*=*0*])

The abstract base class **CCompiler** defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are *verbose* (show verbose output), *dry_run* (don't actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to `0` (off). Note that you probably don't want to instantiate **CCompiler** or one of its subclasses directly - use the **distutils.CCompiler.new_compiler()** factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

add_include_dir(*dir*)

Add *dir* to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to **add_include_dir()**.

set_include_dirs(*dirs*)

Set the list of directories that will be searched to *dirs* (a list of strings). Overrides any preceding calls to **`add_include_dir()`**; subsequent calls to **`add_include_dir()`** add to the list passed to **`set_include_dirs()`**. This does not affect any list of standard include directories that the compiler may search by default.

add_library(*libname*)

Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to **`add_library()`** and/or **`set_libraries()`**. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

set_libraries(*libnames*)

Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

add_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for libraries specified to **`add_library()`** and **`set_libraries()`**. The linker will be instructed to search for libraries in the order they are supplied to **`add_library_dir()`** and/or **`set_library_dirs()`**.

set_library_dirs(*dirs*)

Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the linker may search by default.

add_runtime_library_dir(*dir*)

Add *dir* to the list of directories that will be searched for shared libraries at runtime.

set_runtime_library_dirs(*dirs*)

Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

define_macro(*name*[, *value*=*None*])

Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used.

undefine_macro(*name*)

Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by **`define_macro()`** and undefined by **`undefine_macro()`** the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to **`compile()`**), then that takes precedence.

add_link_object(*object*)

Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of "resource compilers") to be included in every link driven by this compiler object.

set_link_objects(*objects*)

Set the list of object files (or analogues) to be included in every link to *objects*. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU **autoconf**.

detect_language(*sources*)

Detect the language of a given file, or list of files. Uses the instance attributes **`language_map`** (a dictionary), and **`language_order`** (a list) to do the job.

find_library_file(*dirs*, *lib*[, *debug*=*0*])

Search the specified list of directories for a static or shared library file *lib* and return the full path to that file. If *debug* is true, look for a debugging version (if that makes sense on the current platform). Return `None` if *lib* wasn't found in any of the specified directories.

has_function(*funcname*[, *includes*=*None*, *include_dirs*=*None*, *libraries*=*None*, *library_dirs*=*None*])

Return a boolean indicating whether *funcname* is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for libraries.

library_option(*lib*)

Return the compiler option to add *lib* to the list of libraries linked into the shared library or executable.

runtime_library_dir_option(*dir*)

Return the compiler option to add *dir* to the list of directories searched for runtime libraries.

set_executables(***args*)

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the 'executables' class attribute), but most will have:

attribute	description
compiler	C/C++ compiler
linker_so	linker used to create shared objects and libraries
linker_exe	linker used to create binary executables
archiver	static library creator

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See **distutils.util.split_quoted()**.)

The following methods invoke stages in the build process.

compile(*sources*[, *output_dir*=*None*, *macros*=*None*, *include_dirs*=*None*, *debug*=*0*, *extra_preargs*=*None*, *extra_postargs*=*None*, *depends*=*None*])

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

sources must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg.

`MSVCCompiler` can handle resource files in *sources*). Return a list of object filenames, one per source filename in *sources*. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If *output_dir* is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if *output_dir* is *build*, then it would compile to `build/foo/bar.o`.

macros, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

include_dirs, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

debug is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

extra_preargs and *extra_postargs* are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

depends, if given, is a list of filenames that all targets depend on. If a source file is older than any file in

depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises **CompileError** on failure.

create_static_lib(*objects*, *output_libname*[, *output_dir*=*None*, *debug*=*0*, *target_lang*=*None*])

Link a bunch of stuff together to create a static library file. The "bunch of stuff" consists of the list of object files supplied as *objects*, the extra object files supplied to **add_link_object()** and/or **set_link_objects()**, the libraries supplied to **add_library()** and/or **set_libraries()**, and the libraries supplied as *libraries* (if any).

output_libname should be a library name, not a filename; the filename will be inferred from the library name. *output_dir* is the directory where the library file will be put.

debug is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the *debug* flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises **LibError** on failure.

link(*target_desc*, *objects*, *output_filename*[, *output_dir*=*None*, *libraries*=*None*, *library_dirs*=*None*, *runtime_library_dirs*=*None*, *export_symbols*=*None*, *debug*=*0*, *extra_preargs*=*None*, *extra_postargs*=*None*, *build_temp*=*None*, *target_lang*=*None*])

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as *objects*. *output_filename* should be a filename. If *output_dir* is supplied, *output_filename* is relative to it (i.e. *output_filename* can provide directory components if needed).

libraries is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes `libfoo.a` on Unix and `foo.lib` on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

library_dirs, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to **`add_library_dir()`** and/or **`set_library_dirs()`**. *runtime_library_dirs* is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at run-time. (This may only be relevant on Unix.)

export_symbols is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

debug is as for **`compile()`** and **`create_static_lib()`**, with the slight distinction that it actually matters on most platforms (as opposed to **`create_static_lib()`**, which includes a *debug* flag mostly for form’s sake).

extra_preargs and *extra_postargs* are as for **`compile()`** (except of course that they supply command-line arguments for the particular linker being used).

target_lang is the target language for which the given

objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises **LinkError** on failure.

link_executable(*objects*, *output_progname*[, *output_dir*=*None*, *libraries*=*None*, *library_dirs*=*None*, *runtime_library_dirs*=*None*, *debug*=*0*, *extra_preargs*=*None*, *extra_postargs*=*None*, *target_lang*=*None*])

Link an executable. *output_progname* is the name of the file executable, while *objects* are a list of object filenames to link in. Other arguments are as for the **link()** method.

link_shared_lib(*objects*, *output_libname*[, *output_dir*=*None*, *libraries*=*None*, *library_dirs*=*None*, *runtime_library_dirs*=*None*, *export_symbols*=*None*, *debug*=*0*, *extra_preargs*=*None*, *extra_postargs*=*None*, *build_temp*=*None*, *target_lang*=*None*])

Link a shared library. *output_libname* is the name of the output library, while *objects* is a list of object filenames to link in. Other arguments are as for the **link()** method.

link_shared_object(*objects*, *output_filename*[, *output_dir*=*None*, *libraries*=*None*, *library_dirs*=*None*, *runtime_library_dirs*=*None*, *export_symbols*=*None*, *debug*=*0*, *extra_preargs*=*None*, *extra_postargs*=*None*, *build_temp*=*None*, *target_lang*=*None*])

Link a shared object. *output_filename* is the name of the shared object that will be created, while *objects* is a list of object filenames to link in. Other arguments are as for the **link()** method.

preprocess(*source*[, *output_file*=*None*, *macros*=*None*, *include_dirs*=*None*, *extra_preargs*=*None*, *extra_postargs*=*None*])

Preprocess a single C/C++ source file, named in

source. Output will be written to file named *output_file*, or *stdout* if *output_file* not supplied. *macros* is a list of macro definitions as for **compile()**, which will augment the macros set with **define_macro()** and **undefine_macro()**. *include_dirs* is a list of directory names that will be added to the default list, in the same way as **add_include_dir()**.

Raises **PreprocessError** on failure.

The following utility methods are defined by the **CCompiler** class, for use by the various concrete subclasses.

executable_filename(*basename*[, *strip_dir*=*0*, *output_dir*=*''*])

Returns the filename of the executable for the given *basename*. Typically for non-Windows platforms this is the same as the basename, while Windows will get a `.exe` added.

library_filename(*libname*[, *lib_type*=*'static'*, *strip_dir*=*0*, *output_dir*=*''*])

Returns the filename for the given library name on the current platform. On Unix a library with *lib_type* of `'static'` will typically be of the form `liblibname.a`, while a *lib_type* of `'dynamic'` will be of the form `liblibname.so`.

object_filenames(*source_filenames*[, *strip_dir*=*0*, *output_dir*=*''*])

Returns the name of the object files for the given source files. *source_filenames* should be a list of filenames.

shared_object_filename(*basename*[, *strip_dir*=*0*, *output_dir*=*''*])

Returns the name of a shared object file for the given file name *basename*.

execute(*func*, *args*[, *msg*=*None*, *level*=*1*])

Invokes **distutils.util.execute()**. This method

invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry_run* flag.

spawn(*cmd*)

Invokes **distutils.util.spawn()**. This invokes an external process to run the given command.

mkpath(*name*[, *mode*=*511*])

Invokes **distutils.dir_util.mkpath()**. This creates a directory and any missing ancestor directories.

move_file(*src*, *dst*)

Invokes **distutils.file_util.move_file()**. Renames *src* to *dst*.

announce(*msg*[, *level*=*1*])

Write a message using **distutils.log.debug()**.

warn(*msg*)

Write a warning message *msg* to standard error.

debug_print(*msg*)

If the *debug* flag is set on this **CCompiler** instance, print *msg* to standard output, otherwise do nothing.

9.3. distutils.unixccompiler — Unix C Compiler

This module provides the **UnixCCompiler** class, a subclass of **CCompiler** that handles the typical Unix-style command-line C compiler:

- macros defined with **-Dname[=value]**

- macros undefined with **-Uname**
- include search directories specified with **-Idir**
- libraries specified with **-llib**
- library search directories specified with **-Ldir**
- compile handled by **cc** (or similar) executable with **-c** option: compiles `.c` to `.o`
- link static library handled by **ar** command (possibly with **ranlib**)
- link shared library handled by **cc -shared**

9.4. distutils.msvccompiler — Microsoft Compiler

This module provides **MSVCCompiler**, an implementation of the abstract **CCompiler** class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003.

MSVCCompiler will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables *DISTUTILS_USE_SDK* and *MSSdk* must be both set. *MSSdk* indicates that the current environment has been setup by the SDK's `SetEnv.Cmd` script, or that the environment variables had been registered when the SDK was installed; *DISTUTILS_USE_SDK* indicates that the distutils user has made an explicit choice to override the compiler selection by **MSVCCompiler**.

9.5. distutils.bcppcompiler — Borland Compiler

This module provides **BorlandCCompiler**, a subclass of the abstract **CCompiler** class for the Borland C++ compiler.

9.6. distutils.cygwincompiler — Cygwin Compiler

This module provides the **CygwinCCompiler** class, a subclass of **UnixCCompiler** that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).

9.7. distutils.archive_util — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

distutils.archive_util.make_archive(*base_name*, *format*[, *root_dir*=*None*, *base_dir*=*None*, *verbose*=*0*, *dry_run*=*0*])

Create an archive file (eg. `zip` or `tar`). *base_name* is the name of the file to create, minus any format-specific extension; *format* is the archive format: one of `zip`, `tar`, `gztar`, `bztar`, `xztar`, or `ztar`. *root_dir* is a directory that will be the root directory of the archive; ie. we typically `chdir` into *root_dir* before creating the archive. *base_dir* is the directory where we start archiving from; ie. *base_dir* will be the common prefix of all files and directories in the archive. *root_dir* and *base_dir* both default to the current directory. Returns the name of the archive file.

Changed in version 3.5: Added support for the `xztar` format.

distutils.archive_util.make_tarball(*base_name*, *base_dir*[, *compress*=*'gzip'*, *verbose*=*0*, *dry_run*=*0*])

‘Create an (optional compressed) archive as a tar file from all files in and under *base_dir*. *compress* must be `'gzip'` (the default), `'bzip2'`, `'xz'`, `'compress'`, or `None`. For the `'compress'` method the compression utility named by **compress** must be on the default program search path, so this is probably Unix-specific. The output tar file will be named `base_dir.tar`, possibly plus the appropriate compression extension (`.gz`, `.bz2`, `.xz` or `.Z`). Return the output

filename.

Changed in version 3.5: Added support for the `xz` compression.

distutils.archive_util.make_zipfile(*base_name*, *base_dir*[, *verbose*=*0*, *dry_run*=*0*])

Create a zip file from all files in and under *base_dir*. The output zip file will be named *base_name* + `.zip`. Uses either the **`zipfile`** Python module (if available) or the InfoZIP `zip` utility (if installed and found on the default search path). If neither tool is available, raises **`DistutilsExecError`**. Returns the name of the output zip file.

9.8. `distutils.dep_util` — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

distutils.dep_util.newer(*source*, *target*)

Return true if *source* exists and is more recently modified than *target*, or if *source* exists and *target* doesn't. Return false if both exist and *target* is the same age or newer than *source*. Raise **`DistutilsFileError`** if *source* does not exist.

distutils.dep_util.newer_pairwise(*sources*, *targets*)

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (*sources*, *targets*) where source is newer than target, according to the semantics of **`newer()`**.

distutils.dep_util.newer_group(*sources*, *target*[, *missing*='*error*'])

Return true if *target* is out-of-date with respect to any file listed in *sources*. In other words, if *target* exists and is newer

than every file in *sources*, return false; otherwise return true. *missing* controls what we do when a source file is missing; the default (`'error'`) is to blow up with an **OSError** from inside **os.stat()**; if it is `'ignore'`, we silently drop any missing source files; if it is `'newer'`, any missing source files make us assume that *target* is out-of-date (this is handy in "dry-run" mode: it'll make you pretend to carry out commands that wouldn't work because inputs are missing, but that doesn't matter because you're not actually going to run the commands).

9.9. distutils.dir_util — Directory tree operations

This module provides functions for operating on directories and trees of directories.

distutils.dir_util.mkpath(*name*[, *mode*=*0o777*, *verbose*=*0*, *dry_run*=*0*])

Create a directory and any missing ancestor directories. If the directory already exists (or if *name* is the empty string, which means the current directory, which of course exists), then do nothing. Raise **DistutilsFileError** if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If *verbose* is true, print a one-line summary of each mkdir to stdout. Return the list of directories actually created.

distutils.dir_util.create_tree(*base_dir*, *files*[, *mode*=*0o777*, *verbose*=*0*, *dry_run*=*0*])

Create all the empty directories under *base_dir* needed to put *files* there. *base_dir* is just the name of a directory which doesn't necessarily exist yet; *files* is a list of filenames to be interpreted relative to *base_dir*. *base_dir* + the directory portion of every file in *files* will be created if it doesn't already exist. *mode*, *verbose* and *dry_run* flags are as for **mkpath()**.

distutils.dir_util.copy_tree(*src*, *dst*[, *preserve_mode*=*1*, *preserve_times*=*1*, *preserve_symlinks*=*0*, *update*=*0*, *verbose*=*0*, *dry_run*=*0*])

Copy an entire directory tree *src* to a new location *dst*. Both *src* and *dst* must be directory names. If *src* is not a directory, raise **DistutilsFileError**. If *dst* does not exist, it is created with **mkpath()**. The end result of the copy is that every file in *src* is copied to *dst*, and directories under *src* are recursively copied to *dst*. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by *update* or *dry_run*: it is simply the list of all files under *src*, with the names changed to be under *dst*.

preserve_mode and *preserve_times* are the same as for **distutils.file_util.copy_file()**; note that they only apply to regular files, not to directories. If *preserve_symlinks* is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. *update* and *verbose* are the same as for **copy_file()**.

Files in *src* that begin with `.nfs` are skipped (more information on these files is available in answer D2 of the NFS FAQ page [http://nfs.sourceforge.net/#section_d]).

Changed in version 3.3.1: NFS files are ignored.

distutils.dir_util.remove_tree(*directory*[, *verbose*=*0*, *dry_run*=*0*])

Recursively remove *directory* and all files and directories underneath it. Any errors are ignored (apart from being reported to `sys.stdout` if *verbose* is true).

9.10. distutils.file_util — Single file operations

This module contains some utility functions for operating on individual files.

distutils.file_util.copy_file(*src*, *dst*[, *preserve_mode*=*1*, *preserve_times*=*1*, *update*=*0*, *link*=*None*, *verbose*=*0*, *dry_run*=*0*])

Copy file *src* to *dst*. If *dst* is a directory, then *src* is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If *preserve_mode* is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If *preserve_times* is true (the default), the last-modified and last-access times are copied as well. If *update* is true, *src* will only be copied if *dst* does not exist, or if *dst* does exist but is older than *src*.

link allows you to make hard links (using **`os.link()`**) or symbolic links (using **`os.symlink()`**) instead of copying: set it to `'hard'` or `'sym'`; if it is `None` (the default), files are copied. Don't set *link* on systems that don't support it: **`copy_file()`** doesn't check if hard or symbolic linking is available. It uses **`_copy_file_contents()`** to copy file contents.

Return a tuple `(dest_name, copied)`: *dest_name* is the actual name of the output file, and *copied* is true if the file was copied (or would have been copied, if *dry_run* true).

distutils.file_util.move_file(*src*, *dst*[, *verbose*, *dry_run*])

Move file *src* to *dst*. If *dst* is a directory, the file will be moved into it with the same name; otherwise, *src* is just renamed to *dst*. Returns the new full name of the file.

Warning

Handles cross-device moves on Unix using **`copy_file()`**. What about other systems?

distutils.file_util.write_file(*filename*, *contents*)

Create a file called *filename* and write *contents* (a sequence of strings without line terminators) to it.

9.11. `distutils.util` — Miscellaneous other utility functions

This module contains other assorted bits and pieces that don't fit into any other utility module.

distutils.util.get_platform()

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by 'os.uname()'), although the exact information included depends on the OS; e.g., on Linux, the kernel version isn't particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`

For non-POSIX platforms, currently just returns `sys.platform`.

For macOS systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on macOS the architecture value reflects the universal binary status instead of the architecture of the current processor. For 32-bit universal binaries the architecture is `fat`, for 64-bit universal binaries the architecture is `fat64`, and for 4-way universal binaries the architecture is `universal`. Starting from Python 2.7 and Python 3.2 the architecture `fat3` is used for a 3-way universal build (ppc, i386, x86_64) and `intel` is used for a universal build with the i386 and x86_64 architectures

Examples of returned values on macOS:

- `macosx-10.3-ppc`
- `macosx-10.3-fat`
- `macosx-10.5-universal`
- `macosx-10.6-intel`

For AIX, Python 3.9 and later return a string starting with "aix", followed by additional fields (separated by `'-'`) that represent the combined values of AIX Version, Release and Technology Level (first field), Build Date (second field), and bit-size (third field). Python 3.8 and earlier returned only a single additional field with the AIX Version and Release.

Examples of returned values on AIX:

- `aix-5307-0747-32` # 32-bit build on AIX `oslevel -s`: 5300-07-00-0000
- `aix-7105-1731-64` # 64-bit build on AIX `oslevel -s`: 7100-05-01-1731
- `aix-7.2` # Legacy form reported in Python 3.8 and earlier

Changed in version 3.9: The AIX platform string format now also includes the technology level, build date, and ABI bit-size.

distutils.util.convert_path(*pathname*)

Return 'pathname' as a name that will work on the native filesystem, i.e. split it on '/' and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises **`ValueError`** on non-Unix-ish systems if *pathname* either starts or ends with a slash.

distutils.util.change_root(*new_root*, *pathname*)

Return *pathname* with *new_root* prepended. If *pathname* is relative, this is equivalent to `os.path.join(new_root,pathname)` Otherwise, it requires making *pathname* relative and then joining the two,

which is tricky on DOS/Windows.

distutils.util.check_environ()

Ensure that 'os.environ' has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- **HOME** - user's home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see **get_platform()**)

distutils.util.subst_vars(*s*, *local_vars*)

Perform shell/Perl-style variable substitution on *s*. Every occurrence of `$` followed by a name is considered a variable, and variable is substituted by the value found in the *local_vars* dictionary, or in `os.environ` if it's not in *local_vars*. *os.environ* is first checked/augmented to guarantee that it contains certain values: see **check_environ()**. Raise **ValueError** for any variables not found in either *local_vars* or `os.environ`.

Note that this is not a full-fledged string interpolation function. A valid `$variable` can consist only of upper and lower case letters, numbers and an underscore. No { } or ( ) style quoting is available.

distutils.util.split_quoted(*s*)

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

distutils.util.execute(*func*, *args*[, *msg*=*None*, *verbose*=*0*, *dry_run*=*0*])

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the *dry_run* flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the "external action" being performed), and an optional message to print.

distutils.util.strtobool(*val*)

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises **`ValueError`** if *val* is anything else.

distutils.util.byte_compile(*py_files*[, *optimize=0*, *force=0*, *prefix=None*, *base_dir=None*, *verbose=1*, *dry_run=0*, *direct=None*])

Byte-compile a collection of Python source files to `.pyc` files in a `__pycache__` subdirectory (see **PEP 3147** [https://peps.python.org/pep-3147/] and **PEP 488** [https://peps.python.org/pep-0488/]). *py_files* is a list of files to compile; any files that don't end in `.py` are silently skipped. *optimize* must be one of the following:

- `0` - don't optimize
- `1` - normal optimization (like `python -O`)
- `2` - extra optimization (like `python -OO`)

If *force* is true, all files are recompiled regardless of timestamps.

The source filename encoded in each bytecode file defaults to the filenames listed in *py_files*; you can modify these with *prefix* and *basedir*. *prefix* is a string that will be stripped off of each source filename, and *base_dir* is a directory name that will be prepended (after *prefix* is stripped). You can supply either or both (or neither) of *prefix* and *base_dir*, as you wish.

If *dry_run* is true, doesn't actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The *direct* flag is used by the script generated in indirect mode; unless you know what you're doing, leave it set to `None`.

Changed in version 3.2.3: Create `.pyc` files with an `import magic tag` in their name, in a `__pycache__` subdirectory instead of files without tag in the current directory.

Changed in version 3.5: Create `.pyc` files according to **PEP 488** [https://peps.python.org/pep-0488/].

distutils.util.rfc822_escape(*header*)

Return a version of *header* escaped for inclusion in an **RFC 822** [https://datatracker.ietf.org/doc/html/rfc822.html] header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.

9.12. `distutils.dist` — The Distribution class

This module provides the `Distribution` class, which represents the module distribution being built/installed/distributed.

9.13. `distutils.extension` — The Extension class

This module provides the `Extension` class, used to describe C/C++ extension modules in setup scripts.

9.14. `distutils.debug` — Distutils

debug mode

This module provides the DEBUG flag.

9.15. `distutils.errors` — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user's fault (eg. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`.

9.16. `distutils.fancy_getopt` — Wrapper around the standard getopt module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have "negative aliases" — eg. if `--quiet` is the "negative alias" of `--verbose`, then `--quiet` on the command line sets *verbose* to false.

distutils.fancy_getopt.fancy_getopt(*options*, *negative_opt*, *object*, *args*)

Wrapper function. *options* is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. *negative_opt* should be a dictionary mapping option names to option names, both the key and value should be in the *options* list. *object* is an object

which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). *args* is the argument list. Will use `sys.argv[1:]` if you pass `None` as *args*.

distutils.fancy_getopt.wrap_text(*text*, *width*)

Wraps *text* to less than *width* wide.

class distutils.fancy_getopt.FancyGetopt([*option_table*=*None*])

The option_table is a list of 3-tuples: `(long_option, short_option, help_string)`

If an option takes an argument, its *long_option* should have `'='` appended; *short_option* should just be a single character, no `':'` in any case. *short_option* should be `None` if a *long_option* doesn't have a corresponding *short_option*. All option tuples must have long options.

The `FancyGetopt` class provides the following methods:

FancyGetopt.getopt([*args*=*None*, *object*=*None*])

Parse command-line options in args. Store as attributes on *object*.

If *args* is `None` or not supplied, uses `sys.argv[1:]`. If *object* is `None` or not supplied, creates a new `OptionDummy` instance, stores option values there, and returns a tuple `(args, object)`. If *object* is supplied, it is modified in place and `getopt()` just returns *args*; in both cases, the returned *args* is a modified copy of the passed-in *args* list, which is left untouched.

FancyGetopt.get_option_order()

Returns the list of `(option, value)` tuples processed by the previous run of `getopt()` Raises `RuntimeError` if `getopt()` hasn't been called yet.

FancyGetopt.generate_help([*header*=*None*])

Generate help text (a list of strings, one per suggested line of output) from the option table for this `FancyGetopt` object.

If supplied, prints the supplied *header* at the top of the help.

9.17. `distutils.filelist` — The FileList class

This module provides the `FileList` class, used for poking about the filesystem and building lists of files.

9.18. `distutils.log` — Simple PEP 282 [https://peps.python.org/pep-0282/] -style logging

9.19. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.

9.20. `distutils.sysconfig` — System configuration information

Deprecated since version 3.10: `distutils.sysconfig` has been merged into `sysconfig`.

The `distutils.sysconfig` module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the `Makefile` and configuration header that are installed

with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the **`distutils`** package.

distutils.sysconfig.PREFIX

The result of `os.path.normpath(sys.prefix)`.

distutils.sysconfig.EXEC_PREFIX

The result of `os.path.normpath(sys.exec_prefix)`.

distutils.sysconfig.get_config_var(*name*)

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

distutils.sysconfig.get_config_vars(...)

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `None` will be included for that variable.

distutils.sysconfig.get_config_h_filename()

Return the full path name of the configuration header. For Unix, this will be the header generated by the **configure** script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

distutils.sysconfig.get_makefile_filename()

Return the full path name of the `Makefile` used to build Python. For Unix, this will be a file generated by the **configure** script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This

function is only useful on POSIX platforms.

The following functions are deprecated together with this module and they have no direct replacement.

distutils.sysconfig.get_python_inc([*plat_specific*[, *prefix*]])

Return the directory for either the general or platform-dependent C include files. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true.

distutils.sysconfig.get_python_lib([*plat_specific*[, *standard_lib*[, *prefix*]]])

Return the directory for either the general or platform-dependent library installation. If *plat_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of **PREFIX**, or as the exec-prefix instead of **EXEC_PREFIX** if *plat_specific* is true. If *standard_lib* is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the **distutils** package.

distutils.sysconfig.customize_compiler(*compiler*)

Do any platform-specific customization of a **distutils.ccompiler.CCompiler** instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's `Makefile`. This information includes the selected compiler, compiler and linker options, and the

extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

distutils.sysconfig.set_python_build()

Inform the **distutils.sysconfig** module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.

9.21. **distutils.text_file** — The TextFile class

This module provides the **TextFile** class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

class distutils.text_file.TextFile([*filename*=*None*, *file*=*None*, ***options*])

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as # is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a **warn()** method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides **unreadline()** for implementing line-at-a-time lookahead.

TextFile instances are create with either *filename*, *file*, or both. **RuntimeError** is raised if both are `None`. *filename* should be a string, and *file* a file object (or something that provides **readline()** and **close()** methods). It is

recommended that you supply at least *filename*, so that **TextFile** can include it in warning messages. If *file* is not supplied, **TextFile** creates its own using the **open()** built-in function.

The options are all boolean, and affect the values returned by **readline()**

option name	description
strip_comments	strip from `'#'` to end-of-line, as well as any whitespace leading up to the `'#'`—unless it is escaped by a backslash
lstrip_ws	strip leading whitespace from each line before returning it
rstrip_ws	strip trailing whitespace (including line terminator!) from each line before returning it.
skip_blanks	skip lines that are empty *after* stripping comments and whitespace. (If both lstrip_ws and rstrip_ws are false, then some lines may consist of solely whitespace: these will *not* be skipped, even if *skip_blanks* is true.)
join_backslash	if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.
collapse_join	strip whitespace from lines that are joined to their predecessor; only matters if `(join_lines and not lstrip_ws)`

Note that since *rstrip_ws* can strip the trailing newline, the semantics of **readline()** must differ from those of the built-in file object's **readline()** method! In particular, **readline()** returns `None` for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if *rstrip_ws* is true but *skip_blanks* is not.

open(*filename*)

Open a new file *filename*. This overrides any *file* or *filename* constructor arguments.

close()

Close the current file and forget everything we know

about it (including the filename and the current line number).

warn(*msg*[, *line*=*None*])

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as `"lines 3-5"`. If *line* is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

readline()

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been "unread" with **`unreadline()`**). If the *join_lines* option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling **`warn()`** after **`readline()`** emits a warning about the physical line(s) just read. Returns `None` on end-of-file, since the empty string can occur if *rstrip_ws* is true but *strip_blanks* is not.

readlines()

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

unreadline(*line*)

Push *line* (a string) onto an internal buffer that will be checked by future **`readline()`** calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are "unread" with **`unreadline()`** are not subsequently re-cleansed (whitespace stripped, or whatever) when read with **`readline()`**. If multiple calls are made to **`unreadline()`** before a call to **`readline()`**, the lines will be returned most in most

recent first order.

9.22. distutils.version — Version number classes

9.23. distutils.cmd — Abstract base class for Distutils commands

This module supplies the abstract base class **Command**.

class distutils.cmd.Command(*dist*)

Abstract base class for defining command classes, the "worker bees" of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called *options*. The options are declared in **initialize_options()** and defined (given their final values) in **finalize_options()**, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, …), and any options dependent on other options must be computed after these outside influences have been processed — hence **finalize_options()**. The body of the subroutine, where it does all its work based on the values of its options, is the **run()** method, which must also be implemented by every command class.

The class constructor takes a single argument *dist*, a **Distribution** instance.

9.24. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the **distutils.command** package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same

name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you'd copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class **`peel_banana`**, a subclass of **`distutils.cmd.Command`**.

Subclasses of **`Command`** must define the following methods.

Command.initialize_options()

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, **`initialize_options()`** implementations are just a bunch of `self.foo = None` assignments.

Command.finalize_options()

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if *foo* depends on *bar*, then it is safe to set *foo* from *bar* as long as *foo* still has the same value it was assigned in **`initialize_options()`**.

Command.run()

A command's raison d'etre: carry out the action it exists to perform, controlled by the options initialized in **`initialize_options()`**, customized by other commands, the setup script, the command-line, and config files, and finalized in **`finalize_options()`**. All terminal output and filesystem interaction should be done by **`run()`**.

Command.sub_commands

sub_commands formalizes the notion of a "family" of

commands, e.g. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines *sub_commands* as a class attribute; it's a list of 2-tuples `(command_name, predicate)`, with *command_name* a string and *predicate* a function, a string or `None`. *predicate* is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (E.g. `install_headers` is only applicable if we have any C header files to install.) If *predicate* is `None`, that command is always applicable.

sub_commands is usually defined at the *end* of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the **install** command.

9.25. `distutils.command` — Individual Distutils commands

9.26. `distutils.command.bdist` — Build a binary installer

9.27. `distutils.command.bdist_packager` — Abstract base class for packagers

9.28. `distutils.command.bdist_dumb` — Build a "dumb" installer

9.29. `distutils.command.bdist_rpm` — Build a binary distribution as a Redhat RPM and SRPM

9.30. distutils.command.sdist — Build a source distribution

9.31. distutils.command.build — Build all files of a package

9.32. distutils.command.build_clib — Build any C libraries in a package

9.33. distutils.command.build_ext — Build any extensions in a package

9.34. distutils.command.build_py — Build the .py/.pyc files of a package

class distutils.command.build_py.build_py

class distutils.command.build_py.build_py_2to3

Alternative implementation of build_py which also runs the 2to3 conversion library on each .py file that is going to be installed. To use this in a setup.py file for a distribution that is designed to run with both Python 2.x and 3.x, add:

```
try:
    from distutils.command.build_py import build_py
except ImportError:
    from distutils.command.build_py import build_py
```

to your setup.py, and later:

```
cmdclass = {'build_py': build_py}
```

to the invocation of setup().

9.35. distutils.command.build_scripts — Build the scripts of a package

9.36. distutils.command.clean — Clean a package build area

This command removes the temporary files created by **build** and its subcommands, like intermediary compiled object files. With the `--all` option, the complete build directory will be removed.

Extension modules built in place will not be cleaned, as they are not in the build directory.

9.37. distutils.command.config — Perform package configuration

9.38. distutils.command.install — Install a package

9.39. distutils.command.install_data — Install data files from a package

9.40. distutils.command.install_headers — Install C/C++ header files from a package

9.41. distutils.command.install_lib —

Install library files from a package

9.42. distutils.command.install_scripts — Install script files from a package

9.43. distutils.command.register — Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in **PEP 301** [https://peps.python.org/pep-0301/].

9.44. distutils.command.check — Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the **`setup()`** function.

Installing Python Modules (Legacy version)

Author

Greg Ward

Note

The entire `distutils` package has been deprecated and will be removed in Python 3.12. This documentation is retained as a reference only, and will be removed with the package. See the What's New entry for more information.

See also

Installing Python Modules
: The up to date module installation documentation. For regular Python usage, you almost certainly want that document rather than this one.

Note

This document is being retained solely until the `setuptools` documentation at https://setuptools.readthedocs.io/en/latest/setuptools.html independently covers all of the relevant information currently included here.

Note

This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure

alternatives. Refer to the quick recommendations section [https://packaging.python.org/guides/tool-recommendations/] in the Python Packaging User Guide for more information.

Introduction

In Python 2.0, the `distutils` API was first added to the standard library. This provided Linux distro maintainers with a standard way of converting Python projects into Linux distro packages, and system administrators with a standard way of installing them directly onto target systems.

In the many years since Python 2.0 was released, tightly coupling the build system and package installer to the language runtime release cycle has turned out to be problematic, and it is now recommended that projects use the `pip` package installer and the `setuptools` build system, rather than using `distutils` directly.

See Installing Python Modules and Distributing Python Modules for more details.

This legacy documentation is being retained only until we're confident that the `setuptools` documentation covers everything needed.

Distutils based source distributions

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running one command from a terminal:

```
python setup.py install
```

For Windows, this command should be run from a command prompt window (*Start* ▸ *Accessories*):

```
setup.py install
```

If all these things are true, then you already know how to build and install the modules you've just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don't really need this manual. Or rather, the above command is everything you need to get out of this manual.

Standard Build and Install

As described in section Distutils based source distributions, building and installing a module distribution using the Distutils is usually one simple command to run from a terminal:

```
python setup.py install
```

Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -     # unpacks into di
cd foo-1.0
python setup.py install
```

On Windows, you'd probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either an archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as **unzip** or **pkunzip**) to unpack the archive. Then, open a command prompt window and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```

Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build
python setup.py install
```

If you do this, you will notice that running the **install** command first runs the **build** command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the **build** command is responsible for putting the files to install into a *build directory*. By default, this is `build` under the distribution root; if you’re excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the **`--build-base`** option. For example:

```
python setup.py build --build-base=/path/to/pybuild/foo-
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
                temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for "pure module distributions"—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.`*`plat`* directory holds temporary files generated by the compile/link process that don't actually get installed. In either case, the `lib` (or `lib.`*`plat`*) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

How installation works

After the **build** command runs (whether you run it explicitly, or the **install** command does it for you), the work of the **install** command is relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.`*`plat`*) to your chosen installation directory.

If you don't choose an installation directory—i.e., if you just run `setup.py install`—then the **install** command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and macOS, which is also Unix-based), it also depends on

whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

Platform	Default installation location
(1) Unix (pure)	*prefix*`/lib/python`*X.Y*`/site-packages`
(2) Unix (non-pure)	*exec-prefix*`/lib/python`*X.Y*`/site-packages`
(3) Windows	*prefix*`\Lib\site-packages`

Notes:

1. Most Linux distributions include Python as a standard part of the system, so *prefix* and *exec-prefix* are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default *prefix* and *exec-prefix* are `/usr/local`.
2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.

prefix and *exec-prefix* stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and macOS. You can find out what your Python installation uses for *prefix* and *exec-prefix* by running Python in interactive mode and typing a few simple commands. Under Unix, just type `python` at the shell prompt. Under Windows, choose *Start ▸ Programs ▸ Python X.Y ▸ Python (command line)*. Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my *prefix* and *exec-prefix*:

```
Python 2.4 (#26, Aug  7 2004, 17:19:02)
Type "help", "copyright", "credits" or "license" for mor
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

A few other placeholders are used in this document: *X.Y* stands for

the version of Python, for example `3.2`; *`abiflags`* will be replaced by the value of **`sys.abiflags`** or the empty string for platforms which don't define ABI flags; *`distname`* will be replaced by the name of the module distribution being installed. Dots and capitalization are important in the paths; for example, a value that uses `python3.2` on UNIX will typically use `Python32` on Windows.

If you don't want to install modules to the standard location, or if you don't have permission to write there, then you need to read about alternate installations in section Alternate Installation. If you want to customize your installation directories more heavily, see section Custom Installation on custom installations.

Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils **install** command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the **install** command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Note that the various alternate installation schemes are mutually exclusive: you can pass `--user`, or `--home`, or `--prefix` and `--exec-prefix`, or `--install-base` and `--install-platbase`, but you can't mix from these groups.

Alternate installation: the user scheme

This scheme is designed to be the most convenient solution for users that don't have write permission to the global site-packages directory or don't want to install into it. It is enabled with a simple option:

```
python setup.py install --user
```

Files will be installed into subdirectories of **site.USER_BASE** (written as *userbase* hereafter). This scheme installs pure Python modules and extension modules in the same location (also known as **site.USER_SITE**). Here are the values for UNIX, including macOS:

Type of file	Installation directory
modules	*userbase*`/lib/python`*X.Y*`/site-packages`
scripts	*userbase*`/bin`
data	*userbase*
C headers	*userbase*`/include/python`*X.Y*`abiflags/`*distname*

And here are the values used on Windows:

Type of file	Installation directory
modules	*userbase*`\Python`*XY*`\site-packages`
scripts	*userbase*`\Python`*XY*`\Scripts`
data	*userbase*
C headers	*userbase*`\Python`*XY*`\Include\{distname}`

The advantage of using this scheme compared to the other ones described below is that the user site-packages directory is under normal conditions always included in **sys.path** (see **site** for more information), which means that there is no additional step to perform after running the `setup.py` script to finalize the installation.

The **build_ext** command also has a `--user` option to add *userbase*`/include` to the compiler search path for header files and *userbase*`/lib` to the compiler search path for libraries as well as to the runtime search path for shared C libraries (rpath).

Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme’s name is derived from the idea of a “home” directory on Unix, since it’s not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the **`--home`** option. On Unix, lazy typists can just type a tilde (~); the **install** command will expand this to your home directory:

```
python setup.py install --home=~
```

To make Python find the distributions installed with this scheme, you may have to modify Python’s search path or edit **`sitecustomize`** (see **`site`**) to call **`site.addsitedir()`** or edit **`sys.path`**.

The **`--home`** option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

Type of file	Installation directory
modules	`lib/python`
scripts	`bin`
data	*prefix*
C headers	`include/python/`*distname*

(Mentally replace slashes with backslashes if you’re on Windows.)

Alternate installation: Unix (the prefix scheme)

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—

that's why the user and home schemes come before. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of "the system" rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.`*X* rather than `/usr/lib/python2.`*X*. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.`*X*, but those modules would have to be installed to, say, `/mnt/`*`@server`*`/export/lib/python2.`*X*. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@se
```

In either case, the **`--prefix`** option defines the installation base, and the **`--exec-prefix`** option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If **`--exec-prefix`** is not supplied, it defaults to **`--prefix`**. Files are installed as follows:

Type of file	Installation directory
Python modules	*prefix*`/lib/python`*X.Y*`/site-packages`
extension modules	*exec-prefix*`/lib/python`*X.Y*`/site-packages`
scripts	*prefix*`/bin`
data	*prefix*
C headers	*prefix*`/include/python`*X.Y*`abiflags/distname`

There is no requirement that **`--prefix`** or **`--exec-prefix`** actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation

time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with **--prefix** and **--exec-prefix** supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your **--prefix** and **--exec-prefix** don't even point to an alternate Python installation, this is immaterial.)

Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under Unix, the **--prefix** option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the **--prefix** option; the **--exec-prefix** option is not supported under Windows, which means that pure Python modules and extension modules are installed into the same location. Files are installed as follows:

Type of file	Installation directory
modules	*prefix*`\Lib\site-packages`
scripts	*prefix*`\Scripts`

prefix	*prefix*`/include/site/python`*version*`/`*distname*

Custom Installation

Sometimes, the alternate installation schemes described in section Alternate Installation just don't do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a *custom installation scheme*.

To create a custom installation scheme, you start with one of the alternate schemes and override some of the installation directories used for the various types of files, using these options:

Type of file	Override option
Python modules	`--install-purelib`
extension modules	`--install-platlib`
all modules	`--install-lib`
scripts	`--install-scripts`
data	`--install-data`
C headers	`--install-headers`

These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same—they only differ when you use the Unix "prefix scheme" and supply different `--prefix` and `--exec-prefix` options; using `--install-lib` will override values computed or given for `--install-purelib` and `--install-platlib`, and is recommended for schemes that don't make a difference between Python and extension modules.)

For example, say you're installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the **`--install-scripts`** option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home

directory, in this case):

```
python setup.py install --home=~ --install-scripts=scrip
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the **`--install-scripts`** option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the "prefix scheme", where the prefix is whatever your Python interpreter was installed with— `/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of *`prefix`*, rather than right in *`prefix`* itself. This is almost as easy as customizing the script installation directory—you just have to remember that there are two types of modules to worry about, Python and extension modules, which can conveniently be both controlled by one option:

```
python setup.py install --install-lib=Site
```

The specified installation directory is relative to *`prefix`*. Of course, you also have to ensure that this directory is in Python's module search path, such as by putting a `.pth` file in a site directory (see **`site`**). See section Modifying Python's Search Path to find out how to modify Python's search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under `python` in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~ \
```

```
                         --install-purelib=python/lib \
                         --install-platlib=python/lib.$PL
                         --install-scripts=python/scripts
                         --install-data=python/data
```

or, equivalently,

```
python setup.py install --home=~/python \
                         --install-purelib=lib \
                         --install-platlib='lib.$PLAT' \
                         --install-scripts=scripts
                         --install-data=data
```

`$PLAT` is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are *not* equivalent if you supply a different installation base directory when you run the setup script. For

example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as `$PLAT`. (And of course, on systems that don't have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section Distutils Configuration Files for details.

Note

When a virtual environment is activated, any options that change the installation path will be ignored from all distutils configuration files to prevent inadvertently installing projects outside of the virtual environment.

Modifying Python's Search Path

When the Python interpreter executes an **`import`** statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the **`sys`** module and printing the value of `sys.path`.

```
$ python
Python 2.2 (#11, Oct  3 2002, 13:31:27)
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linu
Type "help", "copyright", "credits" or "license" for mor
>>> import sys
```

```
>>> sys.path
['', '/usr/local/lib/python2.3', '/usr/local/lib/python2
 '/usr/local/lib/python2.3/lib-tk', '/usr/local/lib/pyth
 '/usr/local/lib/python2.3/site-packages']
>>>
```

The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the **`site`** module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the **`-S`** switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```
import sys
sys.path.append('/www/python/')
```

However, if you reinstall the same major version of Python

(perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You'd have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. **`PYTHONHOME`** sets an alternate value for the prefix of the Python installation. For example, if **`PYTHONHOME`** is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/plat-linux2', ...]`.

The **`PYTHONPATH`** variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if **`PYTHONPATH`** is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the **`site`** module removes paths that don't exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.

Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from "earlier" files are overridden by "later" files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and macOS, the three configuration files (in the order they are processed) are:

Type of file	Location and filename	Notes

(1)	system	*prefix*`/lib/python`*ver*`/distutils/distutils.cfg`
(2)	personal	`$HOME/.pydistutils.cfg`
(3)	local	`setup.cfg`

And on Windows, the configuration files are:

(4)	system	*prefix*`\Lib\distutils\distutils.cfg`
(5)	personal	`%HOME%\pydistutils.cfg`
(6)	local	`setup.cfg`

On all platforms, the "personal" file can be temporarily disabled by passing the `--no-user-cfg` option.

Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to *prefix*`/lib/python1.5/site-packages/distutils`, so the system configuration file should be put there under Python 1.5.2.
2. On Unix, if the **`HOME`** environment variable is not defined, the user's home directory will be determined with the **`getpwuid()`** function from the standard **`pwd`** module. This is done by the **`os.path.expanduser()`** function used by Distutils.
3. I.e., in the current directory (usually the location of the setup script).
4. (See also note (1).) Under Python 1.6 and later, Python's default "installation prefix" is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.
5. On Windows, if the **`HOME`** environment variable is not defined, **`USERPROFILE`** then **`HOMEDRIVE`** and **`HOMEPATH`** will be tried. This is done by the **`os.path.expanduser()`**

function used by Distutils.

Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as `option=value`.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the **build*** commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the **build** command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the **`--help`** option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using **`--help`** without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.

Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines

have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- *module* is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.
- *sourcefile* is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- *cpparg* is an argument for the C preprocessor, and is anything starting with **`-I`**, **`-D`**, **`-U`** or **`-C`**.
- *library* is anything ending in `.a` or beginning with **`-l`** or **`-L`**.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add **`-lm`** to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the **`-Xcompiler`** *arg* and **`-Xlinker`** *arg* options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after **`-Xcompiler`** and **`-Xlinker`** will be appended to the proper command line, so in the above example the compiler will be passed the **`-o32`** option, and the linker will be passed **`-shared`**. If a compiler option requires an argument, you'll have to supply multiple **`-Xcompiler`** options; for example, to pass `-x c++` the `Setup` file would have to contain `-Xcompiler -x`

`-Xcompiler c++`.

Compiler flags can also be supplied through setting the **`CFLAGS`** environment variable. If set, the contents of **`CFLAGS`** will be added to the compiler flags specified in the `Setup` file.

Using non-Microsoft compilers on Windows

Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library `python25.lib` into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn't find such a special library it uses the default name (`foo.lib`.) 1

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you

could specify this in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

Information about the free C++ compiler from Borland, including links to the download pages.

Creating Python Extensions Using Borland's Free Compiler **[http://www.cyberus.ca/~g_will/pyExtenDL.shtml]**
Document describing how to use Borland's free command-line C++ compiler to build Python.

GNU C / Cygwin / MinGW

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. 2 For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C++ or depend on Microsoft Visual C extensions.

To let Distutils compile your extension with Cygwin you have to type:

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode 3 or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

Older Versions of Python and MinGW

The following instructions only apply if you're using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland's C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at https://sourceforge.net/projects/mingw/files/MinGW/Extension/pexports/).

```
pexports python25.dll >python25.def
```

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a "just for me" installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python2
```

The resulting library has to be placed in the same directory as `python25.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,…) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

See also

Building Python modules on MS Windows platform with MinGW [https://old.zope.dev/Members/als/tips/win32_mingw_modules]
: Information about building the required libraries for the MinGW environment.

Footnotes

1

This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

2

Check https://www.sourceware.org/cygwin/ for more information

3

Then you have no POSIX emulation available, but you also don't need `cygwin1.dll`.

Python Module Index

_ | a | b | c | d | e | f | g | h | i | j | k | l | m | n | o | p | q | r | s | t | u | v | w | x | z

-	
__future__	*Future statement definitions*
__main__	*The environment where top-level code is run. Covers command-line interfaces, import-time behavior, and ``__name__ == '__main__'``.*
_thread	*Low-level threading API.*
a	
abc	*Abstract base classes according to :pep:`3119`.*
aifc	**Deprecated:** *Read and write audio files in AIFF or AIFC format.*
argparse	*Command-line option and argument parsing library.*
array	*Space efficient arrays of uniformly typed numeric values.*
ast	*Abstract Syntax Tree classes and manipulation.*
asynchat	**Deprecated:** *Support for asynchronous command/response protocols.*

asyncio	*Asynchronous I/O.*
asyncore	**Deprecated:** *A base class for developing asynchronous socket handling services.*
atexit	*Register and execute cleanup functions.*
audioop	**Deprecated:** *Manipulate raw audio data.*

b

base64	*RFC 4648: Base16, Base32, Base64 Data Encodings; Base85 and Ascii85*
bdb	*Debugger framework.*
binascii	*Tools for converting between binary and various ASCII-encoded binary representations.*
bisect	*Array bisection algorithms for binary searching.*
builtins	*The module that provides the built-in namespace.*
bz2	*Interfaces for bzip2 compression and decompression.*

c

calendar	*Functions for working with calendars, including some emulation of the Unix cal program.*
cgi	**Deprecated:** *Helpers for running Python scripts via the Common*

	Gateway Interface.
cgitb	**Deprecated:** *Configurable traceback handler for CGI scripts.*
chunk	**Deprecated:** *Module to read IFF chunks.*
cmath	*Mathematical functions for complex numbers.*
cmd	*Build line-oriented command interpreters.*
code	*Facilities to implement read-eval-print loops.*
codecs	*Encode and decode data and streams.*
codeop	*Compile (possibly incomplete) Python code.*
collections	*Container datatypes*
collections.abc	*Abstract base classes for containers*
colorsys	*Conversion functions between RGB and other color systems.*
compileall	*Tools for byte-compiling all Python source files in a directory tree.*
concurrent	
concurrent.futures	*Execute computations concurrently using threads or processes.*
configparser	*Configuration file parser.*
contextlib	*Utilities for with-statement contexts.*
contextvars	*Context Variables*
copy	*Shallow and deep copy operations.*
copyreg	*Register pickle support functions.*
cProfile	

crypt *(Unix)* **Deprecated:** *The crypt() function used to check Unix passwords.*

csv *Write and read tabular data to and from delimited files.*

ctypes *A foreign function library for Python.*

curses *(Unix)* *An interface to the curses library, providing portable terminal handling.*

- **curses.ascii** *Constants and set-membership functions for ASCII characters.*
- **curses.panel** *A panel stack extension that adds depth to curses windows.*
- **curses.textpad** *Emacs-like input editing in a curses window.*

d

dataclasses *Generate special methods on user-defined classes.*

datetime *Basic date and time types.*

dbm *Interfaces to various Unix "database" formats.*

- **dbm.dumb** *Portable implementation of the simple DBM interface.*
- **dbm.gnu** *(Unix)* *GNU's reinterpretation of dbm.*
- **dbm.ndbm** *(Unix)* *The standard "database" interface, based on ndbm.*

decimal *Implementation of the General Decimal*

	Arithmetic Specification.
difflib	*Helpers for computing differences between objects.*
dis	*Disassembler for Python bytecode.*
distutils	*Support for building and installing Python modules into an existing Python installation.*
distutils.archive_util	*Utility functions for creating archive files (tarballs, zip files, ...)*
distutils.bcppcompiler	
distutils.ccompiler	*Abstract CCompiler class*
distutils.cmd	*Provides the abstract base class :class:`~distutils.cmd.Comman* *This class is subclassed by the modules in the distutils.command subpackage.*
distutils.command	*Contains one module for each standard Distutils command.*
distutils.command.bdist	*Build a binary installer for a package*
distutils.command.bdist_dumb	*Build a "dumb" installer - a simple archive of files*
distutils.command.bdist_packager	*Abstract base class for packagers*
distutils.command.bdist_rpm	*Build a binary distribution as a Redhat RPM and SRPM*
distutils.command.build	*Build all files of a package*

distutils.command.build_clib	Build any C libraries in a package
distutils.command.build_ext	Build any extensions in a package
distutils.command.build_py	Build the .py/.pyc files of a package
distutils.command.build_scripts	Build the scripts of a package
distutils.command.check	Check the meta-data of a package
distutils.command.clean	Clean a package build area
distutils.command.config	Perform package configuration
distutils.command.install	Install a package
distutils.command.install_data	Install data files from a package
distutils.command.install_headers	Install C/C++ header files from a package
distutils.command.install_lib	Install library files from a package
distutils.command.install_scripts	Install script files from a package
distutils.command.register	Register a module with the Python Package Index
distutils.command.sdist	Build a source distribution
distutils.core	The core Distutils functionality
distutils.cygwinccompiler	
distutils.debug	Provides the debug flag for distutils
distutils.dep_util	Utility functions for simple dependency checking
distutils.dir_util	Utility functions for operating on directories

	and directory trees
distutils.dist	*Provides the Distribution class, which represents the module distribution being built/installed/ distributed*
distutils.errors	*Provides standard distutils exceptions*
distutils.extension	*Provides the Extension class, used to describe C/C++ extension modules in setup scripts*
distutils.fancy_getopt	*Additional getopt functionality*
distutils.file_util	*Utility functions for operating on single files*
distutils.filelist	*The FileList class, used for poking about the file system and building lists of files.*
distutils.log	*A simple logging mechanism, :pep:`282`-style*
distutils.msvccompiler	*Microsoft Compiler*
distutils.spawn	*Provides the spawn() function*
distutils.sysconfig	*Low-level access to configuration information of the Python interpreter.*
distutils.text_file	*Provides the TextFile class, a simple interface to text files*
distutils.unixccompiler	*UNIX C Compiler*
distutils.util	*Miscellaneous other utility functions*
	Implements classes that

distutils.version	represent module version numbers.
doctest	Test pieces of code within docstrings.

e

email	Package supporting the parsing, manipulating, and generating email messages.
email.charset	Character Sets
email.contentmanager	Storing and Retrieving Content from MIME Parts
email.encoders	Encoders for email message payloads.
email.errors	The exception classes used by the email package.
email.generator	Generate flat text email messages from a message structure.
email.header	Representing non-ASCII headers
email.headerregistry	Automatic Parsing of headers based on the field name
email.iterators	Iterate over a message object tree.
email.message	The base class representing email messages.
email.mime	Build MIME messages.
email.parser	Parse flat text email messages to produce a message object structure.
email.policy	Controlling the parsing and generating of messages

email.utils — Miscellaneous email package utilities.

encodings

encodings.idna — Internationalized Domain Names implementation

encodings.mbcs — Windows ANSI codepage

encodings.utf_8_sig — UTF-8 codec with BOM signature

ensurepip — Bootstrapping the "pip" installer into an existing Python installation or virtual environment.

enum — Implementation of an enumeration class.

errno — Standard errno system symbols.

f

faulthandler — Dump the Python traceback.

fcntl *(Unix)* — The fcntl() and ioctl() system calls.

filecmp — Compare files efficiently.

fileinput — Loop over standard input or a list of files.

fnmatch — Unix shell style filename pattern matching.

fractions — Rational numbers.

ftplib — FTP protocol client (requires sockets).

functools — Higher-order functions and operations on callable objects.

g

gc — Interface to the cycle-

	detecting garbage collector.
getopt	*Portable parser for command line options; support both short and long option names.*
getpass	*Portable reading of passwords and retrieval of the userid.*
gettext	*Multilingual internationalization services.*
glob	*Unix shell style pathname pattern expansion.*
graphlib	*Functionality to operate with graph-like structures*
grp *(Unix)*	*The group database (getgrnam() and friends).*
gzip	*Interfaces for gzip compression and decompression using file objects.*

h

hashlib	*Secure hash and message digest algorithms.*
heapq	*Heap queue algorithm (a.k.a. priority queue).*
hmac	*Keyed-Hashing for Message Authentication (HMAC) implementation*
html	*Helpers for manipulating HTML.*
html.entities	*Definitions of HTML general entities.*

`html.parser`	*A simple parser that can handle HTML and XHTML.*
`http`	*HTTP status codes and messages*
`http.client`	*HTTP and HTTPS protocol client (requires sockets).*
`http.cookiejar`	*Classes for automatic handling of HTTP cookies.*
`http.cookies`	*Support for HTTP state management (cookies).*
`http.server`	*HTTP server and request handlers.*

i

`idlelib`	*Implementation package for the IDLE shell/ editor.*
`imaplib`	*IMAP4 protocol client (requires sockets).*
`imghdr`	**Deprecated:** *Determine the type of image contained in a file or byte stream.*
`imp`	**Deprecated:** *Access the implementation of the import statement.*
`importlib`	*The implementation of the import machinery.*
`importlib.abc`	*Abstract base classes related to import*
`importlib.machinery`	*Importers and path hooks*
`importlib.metadata`	*The implementation of the importlib metadata.*
`importlib.resources`	*Package resource reading, opening, and access*

`importlib.resources.abc`	*Abstract base classes for resources*
`importlib.util`	*Utility code for importers*
`inspect`	*Extract information and source code from live objects.*
`io`	*Core tools for working with streams.*
`ipaddress`	*IPv4/IPv6 manipulation library.*
`itertools`	*Functions creating iterators for efficient looping.*

j

`json`	*Encode and decode the JSON format.*
`json.tool`	*A command line to validate and pretty-print JSON.*

k

`keyword`	*Test whether a string is a keyword in Python.*

l

`lib2to3`	*The 2to3 library*
`linecache`	*Provides random access to individual lines from text files.*
`locale`	*Internationalization services.*
`logging`	*Flexible event logging system for applications.*
`logging.config`	*Configuration of the logging module.*
`logging.handlers`	*Handlers for the logging module.*
`lzma`	*A Python wrapper for*

	the liblzma compression library.
m	
mailbox	*Manipulate mailboxes in various formats*
mailcap	**Deprecated:** *Mailcap file handling.*
marshal	*Convert Python objects to streams of bytes and back (with different constraints).*
math	*Mathematical functions (sin() etc.).*
mimetypes	*Mapping of filename extensions to MIME types.*
mmap	*Interface to memory-mapped files for Unix and Windows.*
modulefinder	*Find modules used by a script.*
msilib *(Windows)*	**Deprecated:** *Creation of Microsoft Installer files, and CAB files.*
msvcrt *(Windows)*	*Miscellaneous useful routines from the MS VC++ runtime.*
multiprocessing	*Process-based parallelism.*
multiprocessing.connection	*API for dealing with sockets.*
multiprocessing.dummy	*Dumb wrapper around threading.*
multiprocessing.managers	*Share data between process with shared objects.*
multiprocessing.pool	*Create pools of processes.*
	Provides shared

multiprocessing.shared_memory	*memory for direct access across processes.*
multiprocessing.sharedctypes	*Allocate ctypes objects from shared memory.*
n	
netrc	*Loading of .netrc files.*
nis *(Unix)*	**Deprecated:** *Interface to Sun's NIS (Yellow Pages) library.*
nntplib	**Deprecated:** *NNTP protocol client (requires sockets).*
numbers	*Numeric abstract base classes (Complex, Real, Integral, etc.).*
o	
operator	*Functions corresponding to the standard operators.*
optparse	**Deprecated:** *Command-line option parsing library.*
os	*Miscellaneous operating system interfaces.*
os.path	*Operations on pathnames.*
ossaudiodev *(Linux, FreeBSD)*	**Deprecated:** *Access to OSS-compatible audio devices.*
p	
pathlib	*Object-oriented filesystem paths*
pdb	*The Python debugger for interactive interpreters.*
pickle	*Convert Python objects to streams of bytes and*

	back.
pickletools	*Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.*
pipes *(Unix)*	**Deprecated:** *A Python interface to Unix shell pipelines.*
pkgutil	*Utilities for the import system.*
platform	*Retrieves as much platform identifying data as possible.*
plistlib	*Generate and parse Apple plist files.*
poplib	*POP3 protocol client (requires sockets).*
posix *(Unix)*	*The most common POSIX system calls (normally used via module os).*
pprint	*Data pretty printer.*
profile	*Python source profiler.*
pstats	*Statistics object for use with the profiler.*
pty *(Unix)*	*Pseudo-Terminal Handling for Unix.*
pwd *(Unix)*	*The password database (getpwnam() and friends).*
py_compile	*Generate byte-code files from Python source files.*
pyclbr	*Supports information extraction for a Python module browser.*
pydoc	*Documentation generator and online*

	help system.
q	
queue	*A synchronized queue class.*
quopri	*Encode and decode files using the MIME quoted-printable encoding.*
r	
random	*Generate pseudo-random numbers with various common distributions.*
re	*Regular expression operations.*
readline *(Unix)*	*GNU readline support for Python.*
reprlib	*Alternate repr() implementation with size limits.*
resource *(Unix)*	*An interface to provide resource usage information on the current process.*
rlcompleter	*Python identifier completion, suitable for the GNU readline library.*
runpy	*Locate and run Python modules without importing them first.*
s	
sched	*General purpose event scheduler.*
secrets	*Generate secure random numbers for managing secrets.*
select	*Wait for I/O completion*

	on multiple streams.
selectors	*High-level I/O multiplexing.*
shelve	*Python object persistence.*
shlex	*Simple lexical analysis for Unix shell-like languages.*
shutil	*High-level file operations, including copying.*
signal	*Set handlers for asynchronous events.*
site	*Module responsible for site-specific configuration.*
smtpd	**Deprecated:** *A SMTP server implementation in Python.*
smtplib	*SMTP protocol client (requires sockets).*
sndhdr	**Deprecated:** *Determine type of a sound file.*
socket	*Low-level networking interface.*
socketserver	*A framework for network servers.*
spwd *(Unix)*	**Deprecated:** *The shadow password database (getspnam() and friends).*
sqlite3	*A DB-API 2.0 implementation using SQLite 3.x.*
ssl	*TLS/SSL wrapper for socket objects*
stat	*Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().*

statistics	*Mathematical statistics functions*
string	*Common string operations.*
stringprep	*String preparation, as per RFC 3453*
struct	*Interpret bytes as packed binary data.*
subprocess	*Subprocess management.*
sunau	**Deprecated:** *Provide an interface to the Sun AU sound format.*
symtable	*Interface to the compiler's internal symbol tables.*
sys	*Access system-specific parameters and functions.*
sysconfig	*Python's configuration information*
syslog *(Unix)*	*An interface to the Unix syslog library routines.*

t

tabnanny	*Tool for detecting white space related problems in Python source files in a directory tree.*
tarfile	*Read and write tar-format archive files.*
telnetlib	**Deprecated:** *Telnet client class.*
tempfile	*Generate temporary files and directories.*
termios *(Unix)*	*POSIX style tty control.*
test	*Regression tests package containing the testing suite for Python.*
test.support	*Support for Python's*

regression test suite.

test.support.bytecode_helper — Support tools for testing correct bytecode generation.

test.support.import_helper — Support for import tests.

test.support.os_helper — Support for os tests.

test.support.script_helper — Support for Python's script execution tests.

test.support.socket_helper — Support for socket tests.

test.support.threading_helper — Support for threading tests.

test.support.warnings_helper — Support for warnings tests.

textwrap — Text wrapping and filling

threading — Thread-based parallelism.

time — Time access and conversions.

timeit — Measure the execution time of small code snippets.

tkinter — Interface to Tcl/Tk for graphical user interfaces

tkinter.colorchooser — Color choosing dialog
(Tk)

tkinter.commondialog — Tkinter base class for dialogs
(Tk)

tkinter.dnd — Tkinter drag-and-drop interface
(Tk)

tkinter.filedialog — Dialog classes for file selection
(Tk)

tkinter.font — Tkinter font-wrapping class
(Tk)

tkinter.messagebox (Tk)	*Various types of alert dialogs*
tkinter.scrolledtext (Tk)	*Text widget with a vertical scroll bar.*
tkinter.simpledialog (Tk)	*Simple dialog windows*
tkinter.tix	*Tk Extension Widgets for Tkinter*
tkinter.ttk	*Tk themed widget set*
token	*Constants representing terminal nodes of the parse tree.*
tokenize	*Lexical scanner for Python source code.*
tomllib	*Parse TOML files.*
trace	*Trace or track Python statement execution.*
traceback	*Print or retrieve a stack traceback.*
tracemalloc	*Trace memory allocations.*
tty (Unix)	*Utility functions that perform common terminal control operations.*
turtle	*An educational framework for simple graphics applications*
turtledemo	*A viewer for example turtle scripts*
types	*Names for built-in types.*
typing	*Support for type hints (see :pep:`484`).*

u

unicodedata	*Access the Unicode*

	Database.
unittest	*Unit testing framework for Python.*
unittest.mock	*Mock object library.*
urllib	
urllib.error	*Exception classes raised by urllib.request.*
urllib.parse	*Parse URLs into or assemble them from components.*
urllib.request	*Extensible library for opening URLs.*
urllib.response	*Response classes used by urllib.*
urllib.robotparser	*Load a robots.txt file and answer questions about fetchability of other URLs.*
uu	**Deprecated:** *Encode and decode files in uuencode format.*
uuid	*UUID objects (universally unique identifiers) according to RFC 4122*
v	
venv	*Creation of virtual environments.*
w	
warnings	*Issue warning messages and control their disposition.*
wave	*Provide an interface to the WAV sound format.*
weakref	*Support for weak references and weak dictionaries.*
webbrowser	*Easy-to-use controller*

	for web browsers.
winreg *(Windows)*	*Routines and objects for manipulating the Windows registry.*
winsound *(Windows)*	*Access to the sound-playing machinery for Windows.*
wsgiref	*WSGI Utilities and Reference Implementation.*
wsgiref.handlers	*WSGI server/gateway base classes.*
wsgiref.headers	*WSGI response header tools.*
wsgiref.simple_server	*A simple WSGI HTTP server.*
wsgiref.types	*WSGI types for static type checking*
wsgiref.util	*WSGI environment utilities.*
wsgiref.validate	*WSGI conformance checker.*

x

xdrlib	**Deprecated:** *Encoders and decoders for the External Data Representation (XDR).*
xml	*Package containing XML processing modules*
xml.dom	*Document Object Model API for Python.*
xml.dom.minidom	*Minimal Document Object Model (DOM) implementation.*
xml.dom.pulldom	*Support for building partial DOM trees from SAX events.*
	Implementation of the

xml.etree.ElementTree	*ElementTree API.*
xml.parsers.expat	*An interface to the Expat non-validating XML parser.*
xml.parsers.expat.errors	
xml.parsers.expat.model	
xml.sax	*Package containing SAX2 base classes and convenience functions.*
xml.sax.handler	*Base classes for SAX event handlers.*
xml.sax.saxutils	*Convenience functions and classes for use with SAX.*
xml.sax.xmlreader	*Interface which SAX-compliant XML parsers must implement.*
xmlrpc	
xmlrpc.client	*XML-RPC client access.*
xmlrpc.server	*Basic XML-RPC server implementations.*
z	
zipapp	*Manage executable Python zip archives*
zipfile	*Read and write ZIP-format archive files.*
zipimport	*Support for importing Python modules from ZIP archives.*
zlib	*Low-level interface to compression and decompression routines compatible with gzip.*
zoneinfo	*IANA time zone support*

Download Python 3.11.1 Documentation

Last updated on: Dec 14, 2022.

To download an archive containing all the documents for this version of Python in one of various formats, follow one of links in this table.

Format	Packed as .zip	Packed as .tar.bz2
PDF (US-Letter paper size)	Download (ca. 13 MiB)	Download (ca. 13 MiB)
PDF (A4 paper size)	Download (ca. 13 MiB)	Download (ca. 13 MiB)
HTML	Download (ca. 9 MiB)	Download (ca. 6 MiB)
Plain Text	Download (ca. 3 MiB)	Download (ca. 2 MiB)
EPUB	Download (ca. 5 MiB)	

These archives contain all the content in the documentation.

Unpacking

Unix users should download the .tar.bz2 archives; these are bzipped tar archives and can be handled in the usual way using tar and the bzip2 program. The InfoZIP unzip program can be used to handle the ZIP archives if desired. The .tar.bz2 archives provide the best compression and fastest download times.

Windows users can use the ZIP archives since those are customary on that platform. These are created on Unix using the InfoZIP zip program.

Problems

If you have comments or suggestions for the Python documentation, please send email to docs@python.org.

Index – A

Argument
Argument (class in argparse)
ArgumentDefaultsHelpFormatter (class in argparse)
ArgumentError (class in argparse)
ArgumentParser (class in argparse)
arguments (inspect.BoundArguments attribute)
